Psychiatry in times of crisis -quo vadis? Mental health and war: the role of Lancet Psychiatry Commission on Mental Health in Ukraine

I. Pinchuk

Institute of Psychiatry, the Taras Shevchenko National University of Kyiv, Kyiv, Ukraine
doi: 10.1192/j.eurpsy.2025.32

Abstract: With both the Russian invasion of Eastern Ukraine and Crimea in 2014, and the war that began in February 2022, Ukraine has faced extensive damage, numerous casualties, widespread displacement of people, and significant psychological trauma. These events have strained health care and, particularly, mental health care systems that were ill-equipped to handle such stresses.

The Commission was created in February 2023, coincident with the first anniversary of the Russian attacks. Prof. Irina Pinchuk was invited to lead The *Lancet Psychiatry* Commission on Mental Health in Ukraine, with Prof. Norbert Skokauskas and Prof. Bennett Leventhal as Co-chairs. The Commission brought together 40 experts in mental health, economics, law, and science from 12 countries, formed into five workgroups (Clinical Services, Clinical Training, Research, Forensics and Legal Advocacy, and Finance).

The Commission recommends a stepped-care model in which low-intensity services are provided by non-specialist personnel, with proper training, integrated in primary care, augmented by digital tools, all directed to moving individuals from institutional to community-based services; Developing a multidisciplinary mental health research infrastructure that is adequately funded and initially focused on relevant issues such as PTSD, the war's impact on Ukrainians, and innovative service models for Ukraine; Policy and legislative changes; Increase in Ukraine's mental health spending, to 4.5% of total healthcare expenditures.

The Lancet Commission supports Ukraine's goals to end the war, provide evidence-based services for its citizens and to join the global community with improved resources clinical education, research, legal structures, funding, and care.

Implementing Primary Prevention into Clinical Practice

C. Arango

Hospital General Universitario Gregorio Marañon, UCM, CIBERSAM, Madrid, Spain
doi: 10.1192/j.eurpsy.2025.33

Abstract: The increasing incidence of mental disorders poses an urgent challenge for psychiatry—one that cannot be addressed by treatment alone. The only sustainable path forward is to **prioritize mental health promotion and primary prevention** at all levels: **universal, selective, and indicated**. While often seen as a long-term investment, primary prevention is **cost-effective** and essential for reducing the future burden of mental illness. This is not science fiction; it is a necessary shift that must happen **now** within our clinical services. In this lecture, I will show how **primary prevention is already being implemented** within the **Institute of Psychiatry and Mental Health in Madrid**, showcasing real-world programs that integrate prevention into everyday psychiatric practice. By embedding prevention into mental healthcare, we can move from a reactive to a proactive model—one that truly addresses the root causes of mental disorders and ensures a healthier future.

Community mental health in Europe: integrate science, practice and lived experience

R. Keet

FIT-academy, GGZ Noord-Holland-Noord, Heerhugowaard, Netherlands
doi: 10.1192/j.eurpsy.2025.34

Abstract: Introduction: The transition from institutional to community-based mental health care has been a key policy goal for decades. Despite progress, challenges such as inadequate funding, political prioritization, and a lack of clear frameworks persist. The European Community Mental Health Services Provider (EUCOMS) Network created a shared vision.
Objectives: EUCOMS aims to outline the principles and key elements for implementing effective community-based mental health care systems. The primary goal is to bridge the gap between evidence, policy, and practice while promoting recovery-oriented, inclusive, and effective care models.
Methods: The development process involved a collaborative, multi-phase approach. Starting with expert workshops and literature reviews, the framework was refined through input from 100 stakeholders, including mental health professionals, researchers, and peer experts across Europe. Structured feedback rounds and consultation workshops further shaped the consensus.
Results: EUCOMS identifies six principles for high-quality community-based mental health care: **Human Rights:** Ensuring dignity, liberty, and equality for all individuals, with a focus on reducing stigma and discrimination. **Public Health:** Adopting a population-based approach to promote mental health and prevent illness. **Recovery:** Supporting personal, functional, and clinical recovery through individualized care. **Effectiveness:** Implementing evidence-based interventions and practices tailored to local contexts. **Community Networks:** Strengthening formal and informal support systems to enhance resilience. **Peer Expertise:** Integrating the lived experiences of service users into service design, delivery, and evaluation. In my presentation I will focus on how these principles are turned into practice in 3 countries in 3 different regions: The Netherlands, Portugal and Ukraine. The Netherlands: the nationwide implementation of the Flexible Assertive Community Treatment model, professionalization of peer expertise and the ecosystem approach on mental health. In Portugal, a nationwide guide for establishing and evaluating community mental health teams in Portugal, promoting integrated, accessible care. In Ukraine, the a nationwide All Ukraine mental Health program was launched during the war, implemented supported by all ministries supported by WHO.
Conclusions: The EUCOMS Network presents a comprehensive framework for regional implementation of community-based mental health services. These principles advocate for systems that are inclusive, recovery-oriented, evidence-based, and integrated within the community. The model requires adaptable implementation, considering cultural, economic, and systemic contexts. Future efforts should focus on stakeholder engagement, capacity building, and sustained advocacy to align policy and practice with these principles.

Online Behavioral Addictions

M. N. Potenza[1,2,3]

[1]Psychiatry; [2]Child Study Center and [3]Neuroscience, Yale School of Medicine, New Haven, United States
doi: 10.1192/j.eurpsy.2025.35

Abstract: Disorders due to addictive behaviors have been included in the eleventh revision of the International Classification of Diseases (ICD-11). Such conditions include gambling disorder

and gaming disorder, and each has online specifiers given the relevance of the internet to each of these conditions in modern societies. This presentation will consider problematic usage of the internet with respect to formally specified disorders (gambling, gaming) as well as other online behaviors (e.g., use of social media) for which problematic engagement may be considered as an "other specified disorder due to addictive behaviors" in the ICD-11. European and global initiatives (e.g., the Lancet Psychiatry Commission on Problematic Usage of the Internet and the development of screening and diagnostic instruments involving World Health Organization workgroups) will be discussed. Clinical, developmental and public health implications will be presented to provide an up-to-date understanding of rapid changes in this area.

New conceptualization of suicidal behaviour

M. Nordentoft[1,2]

[1]Copenhagen Research Center for Mental Health, Mental Health Center and [2]Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark
doi: 10.1192/j.eurpsy.2025.36

Abstract: Suicide is a huge public health problem with 700,000 deaths per year. United Nations are aiming to reduce suicide rates with 33 percent before 2030. Some countries have experienced declining trends, especially in Asia, partly due to restrictions in access to highly lethal pesticides. USA are facing increasing trends and in many western European countries there has been declining tendencies, but most recently rates have been rather stable.
Suicide preventive strategies have focused on universal prevention, thus intervention targeting the who population, selective prevention aiming to reduce risk in different high risk groups, and indicated prevention targeting people who are already having suicidal behavior. In most cases, suicidal acts are carried out within a short period of time, and in many cases without a long period of warning signals. In a way, suicidal acts resemble heart attacks or epileptic episodes more than other complications that often develop slowly and gradually. This makes the task of creating awareness programmes even more difficult.
However, a thorough mapping of risk groups and risk situations will enable us to plan a more targeted intervention. Thus, epidemiology and clinical research can play together.
The most important task is to identify those of immediate risk of suicide and provide treatment and support. There are four distinct risk groups with a very high suicide rate. These are 1) people sent home from psychiatric emergency room visits, 2) people recently discharged from psychiatric hospitalization 3) people who were hospitalized due to attempted suicide 4) people who have called lifeline or other NGO-driven helplines because of suicidal thoughts. It can be helpful to evaluate the population attributable risk associated with different risk factors. The population attributable risk is an estimate of the proportion of the problem that could be avoided if the increased risk in a specific risk group could be reduced to the level of the general population. All these four groups have a very high risk of suicide and together they accounted for 25 - 50 percent of all suicides in Denmark, and the help they are offered are in most countries fragmented and not well organized. Coherent and assertive interventions are needed in order to reduce suicide rates. Interventions will need to involve monitoring persons in high-risk groups for longer periods.
All mental disorders are associated with increased risk of suicide, especially the first years after first hospital contact.
Safety plans have proven to be an effective tool for suicide prevention, and this concept will be presented

The social determinants of mental health: new insights for mental health professionals

J. B. Kirkbride

Division of Psychiatry, UCL, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.37

Abstract: People exposed to more unfavourable social circumstances are more vulnerable to poor mental health over their life course, in ways that are often determined by structural factors which generate and perpetuate intergenerational cycles of disadvantage and poor health. Addressing these challenges has become an imperative matter of social justice. In this paper we provide a roadmap to address the social determinants that cause mental ill health. Relying as far as possible on high-quality evidence, we first map out the literature that supports a causal link between social determinants and later mental health outcomes. Given the breadth of this topic, we focus on the most pervasive social determinants across the life course, and those that are common across major mental disorders. We draw primarily on the available evidence from the Global North, acknowledging that other global contexts will face both similar and unique sets of social determinants that will require equitable attention. Much of our evidence focuses on mental health in groups who are marginalized, and thus often exposed to a multitude of intersecting social risk factors. These groups include refugees, asylum seekers and displaced persons, as well as ethnoracial minoritized groups; lesbian, gay, bisexual, transgender and queer (LGBTQ+) groups; and those living in poverty. We then introduce a preventive framework for conceptualizing the link between social determinants and mental health and disorder, which can guide much needed primary prevention strategies capable of reducing inequalities and improving population mental health. Following this, we provide a review of the evidence that has tested candidate preventive strategies to intervene on social determinants of mental health. These interventions fall broadly within the scope of universal, selected and indicated primary prevention strategies, but we also briefly review important secondary and tertiary strategies to promote recovery in those with existing mental disorders. Finally, we provide seven key recommendations, framed around social justice, which constitute a roadmap for action in research, policy and public health. Adoption of these recommendations would provide an opportunity to advance efforts to intervene on modifiable social determinants that affect population mental health.

Use of smartphone and social media under 15 year should be forbidden/ regulated - Con Speaker

T. van Amelsvoort

Psychiatry & Neuropsychology, Maastricht University, Maastricht, Netherlands
doi: 10.1192/j.eurpsy.2025.38

Abstract: Worldwide, social media and touch screen device use has rapidly increased over the past decade and are particularly popular among young people. To obtain more insight in the potential negative associations with compulsive social media use and touch screen devices in Dutch children, we assessed its relation with self-reported well-being and cognitive function in primary school children. We found social media to be negatively associated with life satisfaction and increasing touch screen device use with increased reaction time. This suggests that the compulsive social media use and touch screen device use have negative consequences on mental well being and cognitive performance already at a young age. Therefore the use of social media in children under the age of 15 years should be restricted or forbidden.

Do we need psychiatric asylums again? - Pro Speaker

M. Martin-Carrasco

Psychiatry, Clinica Psiquiatrica Padre Menni, Pamplona, Spain
doi: 10.1192/j.eurpsy.2025.39

Abstract: Currently, there are few affordable, high-quality long-term care options available for a significant segment of people with serious mental disorders. This population includes adults characterized as poor insight, chronically ill, lacking autonomy, consuming drugs, and severe behavioural disturbances. These individuals frequently suffer from schizophrenia, bipolar disorder, toxic psychosis, severe personality disorders and substance abuse disorder, comorbidity being common. The void is ethically unacceptable and societally costly. Progressive reformers, consumers, civil libertarians, and health economists all advocated for a similar goal—the closure of publically funded psychiatric institutions. But deinstitutionalization has actually been trans-institutionalization. As psychiatric hospitals closed, patients with chronic psychiatric illnesses who lacked family support were moved into nursing homes or other forms of non-specialized residential care, occasionally visiting the psychiatric units of general hospitals. Many became homeless and intermittently used hospital emergency services for urgent care. Most disturbingly, prisons have become the largest mental health care facilities in some countries. The number of people affected may increase as a result of the crisis of the family institution, immigration and the epidemic of drug use.
Realistically, the deployment of both private and public resources is now imperative to provide appropriate care for a number of seriously mentally ill persons. They deserve a safe place to live with proper supports—not cycling between the streets, emergency departments, and prisons. Of course, psychiatric hospitals are a necessary but not sufficient component of a reformed spectrum of psychiatric services, where palliative psychiatry should have a role. A return to asylum based long-term psychiatric care will not remedy the complex problems of the mental health system, especially for patients with milder forms of mental illness who can thrive with high quality outpatient care. However, reforms that ignore the importance of expanding the role of such institutions will fail mental health patients who cannot safely live alone or care for themselves.

DB003

Should we consider assisted suicide a clinically and ethically valuable option for people with mental disorders? - Pro Speaker

T. Pollmaecher[1,2]

[1]Center of Mental Health, Klinikum Ingolstadt, Ingolstadt and [2]Department of Psychiatry, Ludwig Maximilians University, Munich, Germany
doi: 10.1192/j.eurpsy.2025.40

Abstract: In some European and non-European countries assisted suicide (AS), defined as supporting a person in committing suicide by providing e.g. a lethal dose of pentobarbital, is a common practice since decades. In most of these countries, AS initially was considered legitimate only, if a person has a limited expected survival time and/or suffers in an unbearable manner. Hence, AS was implicitly or explicitly not available for persons with psychiatric disorders.
Meanwhile, however, in some countries psychiatric disorders are acknowledged to cause unbearable suffering in certain cases and, in addition, a ruling of the highest court of Germany stated in 2020 that the right to seek suicide assistance might not be restricted to certain conditions or diseases, but solely tied to the competence to freely choose to end ones own life.
Because there is no indication that psychiatric disorders in general render affected person incompetent to freely choose suicide, a general exclusion of affected individuals from AS is incompatible with the biomedical principle of justice.
Clinically, however, psychiatric disorders in persons seeking AS must be seriously taken into account when a judgement has to be made on the individuals' competence to choose freely. This kind of judgements are particularly difficult because both, the persons competence and his or her will to seek AS might be quite variable across time.

DB004

Should we consider assisted suicide a clinically and ethically valuable option for people with mental disorders? Con Speaker

J. Samochowiec

Deptartment of Psychiatry, Pomeranian Medical University, Szczecin, Poland
doi: 10.1192/j.eurpsy.2025.41

Abstract: Several challenges exist rendering people with mental disorders particularly vulnerable to wrongful assisted suicide. Their desire to die may be a symptom of the mental illness rather than an autonomous choice; their decision-making competence may be compromised by the illness and hence more troublesome to determine; the severity of suffering may be more challenging to assess from an external perspective; the very wish to die may be variable over time; and prognostic uncertainty in mental illness may impede determining of whether severe suffering is, in fact, resistant to treatment. An ethically sound argument for excluding people with mental disorders from assisted suicide is their potential inability to make a free, autonomous decision. A person's request for assisted suicide should be considered in the context of an assessment of their capacity to make a well-informed and deliberated decision. Opponents of legalising euthanasia and assisted suicide agree that the suffering caused by mental illness can be just as severe and agonising as in cases of somatic conditions. However, one cannot with all certainty assume that the illness is incurable and that the suffering cannot be minimised to such an extent that the patient experiences relief. The task of psychiatry is to prevent suicide. What follows is that diseases such as depression should be treated, while the patients should be supported and not facilitated to part with their lives. Considering their potentially illness-affected request for suicide, it seems better to prolong their suffering than let them die. One cannot grant the right to die to all those who have the competence to make decisions. Furthermore, legalising euthanasia and assisted suicide also in the case of patients with mental illnesses risks distorting the doctor-patient relationship. Euthanasia is not a balance between the interest of the state and the benefit of the individual in terms of choosing the time and manner of their death. What happens if the interest of the state is not to protect the lives of citizens, especially the most vulnerable and defenceless, including the mentally ill? Once values are rejected, only practical 'benefits' remain, such as financial savings on psychiatric care and treatment. And this is extremely risky. Drawing a clear line in the light of the above considerations seems to be impossible. In the current situation, where many people are exposed to mental suffering, e.g. in the form of depression, the priorities are suicide prevention policies and funding programmes for psychiatric treatment. The debate will take into account arguments for and against euthanasia in patients with mental disorders.

DB005

Do we need psychiatric asylums again? - Con speaker

R. Keet

GGZ Noord-Holland-Noord, Overveen, Netherlands
doi: 10.1192/j.eurpsy.2025.83

Abstract: The expansion of institutional long-term psychiatric care, while well-intentioned, repeats the historical failures of the 19th century answer to severe mental illness: asylums—facilities often marred by neglect, abuse, and the marginalization of individuals with mental illness. Many of the handicaps of persons living in these asylums were not the consequence of the mental health disorder but were iatrogenic damage done by living in these asylums. Though modern psychiatric institutions are more regulated, institutionalization inherently limits autonomy and reinforces stigma, undermining recovery-oriented models of care. Instead of diverting resources to rebuild large-scale facilities, investment should focus on strengthening community-based services, supportive housing, individual placement and support and integrated care models that empower individuals with serious mental illness to live fulfilling lives within society. Evidencebased outpatient programs, Flexible Assertive Community Treatment teams, peer support networks, recovery colleges, mobile crisis teams, peer farms, respite houses offer more humane, cost-effective, and person-centered alternatives. Addressing systemic challenges—such as poverty, lack of housing, lack of social connectedness and fragmented healthcare systems—can better serve this population without reverting to institutional confinement. Long-term solutions must prioritize dignity, autonomy, and inclusion rather than a return to segregated care.

Addiction

J. G. Bramness

Group of Psychiatric Research, UiT The Arctic University of Norway, Tromsø, Norway
doi: 10.1192/j.eurpsy.2025.82

Abstract: Bach et al (2024) investigated in a study published in Biological Psychiatry the effects of psychosocial stress on brain activation in individuals with alcohol use disorder (AUD), finding that stress heightened alcohol cue-induced activation in the left anterior insula, a region associated with salience attribution and goal-directed behavior. The activation correlated with alcohol craving and subsequent alcohol use, suggesting a neurobiological mechanism linking stress, cue reactivity, and relapse. Hassen et al (2024) performed a multi-center study examining cocaine use across Europe, revealing prevalence rates with a general upward trend, particularly among youth, marginalized groups, and opiate-dependent individuals. The study was published in European Addiction Research. Leonhardt et al (2024) investigated individuals with co-occurring substance use disorder and mental illness during the COVID-19 pandemic in Norway and found dramatically higher all-cause mortality rates, despite no increased risk of SARS-CoV-2 infection. This excess mortality highlights the vulnerability of this population and suggests that factors beyond the virus itself contributed to their elevated death rates. The study of Qeadan et al (2024) published in Addiction was one of many studies indicating that GIP/GLP-1 receptor agonist were effective against alcohol and other abuse. This study found lower rates of opioid overdose and alcohol intoxication. The findings support the use of these drugs at least in AUD.

JS001

Public mental health: An opportunity to support collaborative action

M. Destoop[1,2]

[1]CAPRI, Antwerp University and [2]Multiversum, Antwerp, Belgium
doi: 10.1192/j.eurpsy.2025.60

Abstract: Public mental health (PMH) involves a population-based approach to improve coverage, outcomes and coordination of PMH interventions to treat mental health conditions, to prevent associated burden, to prevent mental health conditions from arising, and promote mental well-being and resilience. Collaborative care models involve population-based care teams sharing a defined group of patients tracked in a registry to ensure no one falls through the cracks. Practices track and reach out to patients who are not improving or who do not seek help (yet).

Professional burnout in primary care workforce

F. Petrazzuoli

WONCA Europe, Ruviano, Italy
doi: 10.1192/j.eurpsy.2025.62

Abstract: The so called "silver tsunami" i.e. the unprecedented increase in the number of older patients often affected by multimorbidity is a serious health and socioeconomic concern for modern societies and the interconnected challenges of huge workload, premature burnout, and the shortage of primary care personnel represent a pressing issue for the near future. Addressing the complexity of this issue requires a comprehensive approach due to the scarcity of healthcare professionals in European primary care. The health and well-being of both the primary care workforce and the communities they serve are intrinsically intertwined. Enhancing working conditions is a priority: addressing issues like long hours, heavy workloads, bureaucratic demands, and burnout can enhance the appeal of rural primary care practice, attracting and retaining more professionals. Wonca Europe is actively involved in addressing this issue: in June 2023 at the WONCA Europe 2023 Conference in Brussels with the statement Shortage of European Primary Health Care Workforce and in October 2023 at the 73rd Session of the WHO Regional Committee for Europe, Astana, Kazakhstan. Policymakers, healthcare organizations and professional associations need to collaborate to develop tailored solutions that address the unique challenges faced in each region. By addressing the workload of primary care doctors and other professionals, we can enhance their professional satisfaction, improve patient outcomes, and strengthen primary care as a whole.

The role of psychiatrists in policy forums

M. Rojnic Kuzman

Zagreb University Hospital Centre, Zagreb, Croatia
doi: 10.1192/j.eurpsy.2025.63

Abstract: On its 40th anniversary, the European Psychiatric Association (EPA) held a ceremony at the EU Parliament on December 6, 2023, and published the *Manifesto for the EU Elections* in preparation for the upcoming EU elections in June 2024.
This manifesto outlines the key goals and priorities for advancing mental health in the EU, emphasizing the vital role of psychiatrists in shaping policies and initiatives. The presentation will focus on five main topics, highlighting the involvement of psychiatrists at the European level. These include the harmonization of mental health care delivery, the improvement of working conditions and addressing the shortage of the Mental health workforce, the promotion and harmonization of ethical standards, developing new answers to an evolving World, and promotion of research and implementation of public mental health and prevention measures.
Beyond these overarching European priorities, psychiatrists are actively engaged in national policy forums, addressing a range of issues—from developing comprehensive mental health strategies to tackling specific concerns related to vulnerable populations, children, legal aspects of treatment, and more. Achieving synergy between national and international policy efforts is crucial for the successful implementation of these initiatives, which remains the core objective of this work.

Reporting of psychotherapeutic methods in psychedelic treatments: on the road to ethical, professional and regulatory oversight

A. Oliveira-Maia[1,2]

[1]Champalimaud Foundation and [2]NOVA Medical School, Lisbon, Portugal
doi: 10.1192/j.eurpsy.2025.64

Abstract: The potential of psychedelic substances to treat mental illness is of significant clinical and societal interest, leading to academic and industry-based research to test their effects. Partly, such research was conducted to fulfil requirements of government agencies such as the European Medicines Agency (EMA) and the Food and Drug Administration (FDA), that have started defining requirements and pathways to regulate psychedelic treatments. It is expected that such requirements will involve elements related to psychotherapeutic components of such treatments, which will require standardized reporting of such methods. Here, I will present the results of a systematic review summarising the quality of reporting on psychological interventions in original studies on psychedelic-assisted psychotherapy. We reviewed 45 studies assessing psilocybin, 3,4-methylenedioxymethamphetamine (MDMA), lysergic acid diethylamide (known as LSD), or ayahuasca, for the treatment of mental disorders. Our findings support that psychological interventions were done heterogeneously across studies, and completeness of information reported about these interventions was mostly low, according to an adaptation of the Template for Intervention Description and Replication checklist. In studies including MDMA, psychotherapy was more homogeneous and more procedural details were provided. We thus propose that improved reporting on psychological interventions of psychedelic treatments are necessary to support replicability, generalisability,

and accurate interpretation of research. Furthermore, improved reporting practices are expected to enhance feasibility and safety of future clinical research and real-world implementation of treatments.

Applications of psychedelics in small doses and alternative treatments in psychiatry

K. P. Kuypers

Neuropsychology and Psychopharmacology, Maastricht University, Maastricht, Netherlands
doi: 10.1192/j.eurpsy.2025.65

Abstract: Several years ago, the first studies were conducted in which the effects of psychedelics in low doses were tested in healthy participants. These studies focused mainly on the acute effects of LSD. Questions that remained unanswered were whether low doses have lasting effects, as well as whether they can reduce symptoms of ADHD. To answer these questions, we conducted two studies, administering LSD (15 mcg) repeatedly over 2 weeks to healthy participants and administering LSD (20 mcg) repeatedly over 6 weeks to participants with ADHD. The latter study was a multicenter trial conducted by Universitatsspital (Basel) and Maastricht University. Based on the findings of both studies, we have now planned a follow-up study in 100 individuals with ADHD who also have problems with emotion regulation and/or sleep, to get closer to an "average" ADHD population. This study, which will start later this year, aims to find markers of treatment response. Lastly, plans for a study investigating high-ventilation breathwork as a novel intervention for individuals with social anxiety symptoms will be presented. High-ventilation breathwork has the potential to induce altered states of consciousness similar to those elicited by psychedelics. This research aims to explore its therapeutic potential as a non-pharmacological alternative to psychedelics in psychiatric treatment.

Disclosure of Interest: K. Kuypers Grant / Research support from: Part of the work that is presented is funded by Mindmed Inc (LSD, ADHD), the Beckley Foundation (LSD, healthy volunteers), and grants from the Dutch research organisation (LSD, ADHD, biomarkers) and the Tiny Blue Dot Foundation (Breathwork, Social Anxiety).

EPA position paper

M. Destoop[1,2]

[1]CAPRI, Antwerp University and [2]Multiversum, Antwerp, Belgium
doi: 10.1192/j.eurpsy.2025.66

Abstract: The EPA acknowledges both the therapeutic potential of psychedelic substances and the challenges for both research and clinical implementation. Steps need to be taken towards a well-balanced policy based upon sound scientific evidence and research, aiming at safe, ethical responsible integration of psychedelic therapy available for all patients who can potentially benefit. In the EPA policy paper the importance of the psychosocial components of the treatment as well as the ethical and professional aspects playing a role in real-world implementation, are highlighted. Four recommendations are formulated for further research and clinical implementation.

Using advanced neuroimaging and bioinformatics methods to study brain-behaviour relationships

S. Frangou[1,2]

[1]Psychiatry, Icahn School of Medicine at Mount Sinai, New York, United States and [2]Psychiatry, University of British Columbia, Vancouver, Canada
doi: 10.1192/j.eurpsy.2025.67

Abstract: Understanding the complex relationships between brain structure, function, and behavior is a central challenge in neuroscience. This presentation aims to showcase the transformative potential of neuroimaging and bioinformatics in bridging the gap between neural mechanisms and behavior, ultimately advancing our understanding of the human brain and informing precision medicine. Recent advancements in neuroimaging and bioinformatics enable researchers to explore these relationships with unprecedented precision and scale. This presentation will provide an overview of how neuroimaging modalities can be integrated with advanced bioinformatics tools, including machine learning to uncover novel brain-behavior associations. We will discuss key applications of these methods for neuropsychiatric disorders and specific examples will be used to highlight how combining neuroimaging data with bioinformatics pipelines enhances our ability to measure brain organization at the level of a single individual. Additionally, challenges such as data complexity, standardization, and interpretability will be addressed, alongside strategies to overcome them.

The Precision Psychiatry Roadmap: towards a biology-informed framework for mental disorders

M. Kas

Groningen Institute for Evolutionary Life Sciences, University of Groningen, Groningen, Netherlands
doi: 10.1192/j.eurpsy.2025.68

Abstract: Measuring biology is considered the cornerstone of diagnosis in medicine. For example, we have blood tests to diagnose auto-immune diseases, such as rheumatoid arthritis or lupus. Also, cancer patients with, for example, colon cancer, will receive personalized treatments following biomarker diagnostics of their tumor. In contrast, current classification methodologies for mental

disorders are based on signs and symptoms. These classification systems provide a uniform language to assess psychiatric and neurological disorders across the globe. Clinicians use these diagnoses to communicate with their patients and with other clinicians, and to request, when applicable, reimbursement from payers. Unfortunately, currently available psychotherapies and pharmacotherapies work only in a small proportion of patients within these diagnostic categories. This clinical heterogeneity in treatment response within diagnostic categories is likely explained by biological variation between patients that is not being accounted for in the current classification system for mental disorders. In addition, there is transdiagnostic overlap allowing for novel opportunities to develop innovative quantitative biological endpoints and treatments beyond the current diagnostic framework. The European College of Neuropsychopharmacology (ECNP) New Frontiers meeting 2024 addressed these issues, and indicated a high need for a biology-informed framework to establish more precise diagnosis and treatment for mental disorders. The ECNP, following the 2024 New Frontiers Meeting, is coordinating a global initiative to design and implement a Precision Psychiatry Roadmap. By mobilizing resources and harmonizing translational methodologies and datasets, the aim is to discuss, design, and implement an iterative framework that incorporates biology-informed evidence into symptom-based syndromes, allowing for more discovery and implementation of mechanism-based effective treatments for mental disorders.

The research domain criteria (RDoC) project as a biological framework for research on mental disorders

C. Sanislow

Wesleyan University, Essex, United States
doi: 10.1192/j.eurpsy.2025.69

Abstract: The U.S. National Institute of Mental Health (NIMH) Research Domain Criteria (RDoC) offers a framework to facilitate clinical research for psychopathology. Unique features include an emphasis on transdiagnostic dimensions spanning normal and abnormal ranges of function, novel independent variables (mechanisms, not diagnoses), and the integration of different kinds of observations (neural, psychological, self-report). In this talk, principles and pragmatics of RDoC approach are illustrated with examples from RDoC-framed clinical research, and the clinical significance is discussed.

Suicide and self-harming behaviour in Europe: Current trends and prospects

P. A. Saiz[1,2,3,4]

[1]Departmen of Psychiatry, University of Oviedo; [2]CIBERSAM; [3]ISPA and [4]SESPA, Oviedo, Spain
doi: 10.1192/j.eurpsy.2025.70

Abstract: Suicide and self-harming behaviors represent significant public health challenges across Europe, with profound implications for individuals, families, and communities. This presentation aims to explore current trends in suicide and self-harm, highlighting variations across different European countries and demographic groups. Recent data indicate a concerning rise in self-harming behaviors, particularly among adolescents and young adults, often linked to factors such as mental health disorders, social isolation, and the impact of the COVID-19 pandemic. Furthermore, the stigma surrounding mental health issues continues to hinder open discussions and access to care, exacerbating the problem.Looking ahead, this presentation will propose future directions for research and practice, advocating for a multidisciplinary approach that integrates psychological, social, and medical perspectives. By fostering collaboration among healthcare providers, policymakers, and community organizations, we can enhance our understanding of suicide and self-harm, ultimately leading to more effective prevention and intervention strategies. This session aims to stimulate dialogue and inspire innovative solutions to address these pressing issues in Europe, promoting mental well-being and reducing the incidence of suicide and self-harming behaviors.

The mental health of the child and youth population in Europe: Prevention as paradigm

C. M. Díaz-Caneja

Institute of Psychiatry and Mental Health, Hospital General Universitario Gregorio Marañón, Madrid, Spain
doi: 10.1192/j.eurpsy.2025.71

Abstract: Youth mental health is under significant strain, with long-lasting impacts on European citizens and societies. Alleviating this burden requires a preventive approach. We will review current preventive strategies for youth mental health, including school-based universal, selective, and indicated primary prevention interventions. Additionally, we will discuss novel care systems for youth mental health currently available across Europe and their potential for implementation in various settings.

JS013

Drug use and abuse in Europe: Mental health consequences

A. Schellekens

Psychiatry, Radboudumc, Nijmegen, Netherlands
doi: 10.1192/j.eurpsy.2025.72

Abstract: Substance use is an onging public health burden. As a result all psychiatrists encounter patients with substance use and addictive disorders, either as primary mental health issue, or as co-occurring with other mental health issues. In this presentation, first trends in substance use across Europe will be presented, based on findings from the **European Union Drugs Agency (EUDA). Next, findings on co-occurring other mental health issues will be discussed, with a focus on co-occurring Attention Deficit Hyperactivy Disorder (ADHD). Recent findings from the International Colaboration on ADHD and Substance Abuse (ICASA) will be shared.** ICASA's most recent work was the longitudinal International Naturalistic Cohort Study of ADHD and Substance Use Disorders (SUD). Nearly 600 patients with both ADHD and SUD in treatment were followed for nine months. About two thirds of participants received some kind of ADHD treatment, with half receiving pharmacologic treatment, one third receiving psychological treatment, and only one-fifth receiving combined pharmacologic and psychological treatment. Higher ADHD symptom severity and sobriety at intake were associated with receiving ADHD treatment. These findings suggest that treatment of SUD and ADHD is suboptimal. The implementation of ICASA's consensus statements on diagnosis and treatment of co-occurring ADHD and SUD could help improve quality of care for these individuals.

Hot topics in psychiatry/psychopharmacology

P. Mohr[1,2]

[1]National Institute of Mental Health - CZ, Klecany and [2]3rd Faculty of Medicine, Charles University, Prague, Czech Republic
doi: 10.1192/j.eurpsy.2025.73

Abstract: Psychiatry faces numerous challenges that significantly affect mental health of people in Europe, from climate change, wars, migration, pandemics, to rapid advance of artificial intelligence. Among the most pressing issues are deteriorating mental health of children and adolescents and the lack of trained professionals. At the same time, progress in neuroscientific research contributes to the development of new effective treatments, e.g., monoclonal antibodies for Alzheimer's disease; repurposing of drugs for psychiatric disorders, such as GLP-1 agonists, showed potential in treatment of alcohol addiction. There is also a renewed interest in psychedelics, recent studies verified their therapeutic efficacy in treatment of several mental disorders. Neurostimulation methods (rTMS, tDSC) are recognized non-pharmacological interventions; utilization of new technologies (AI, virtual reality, mobile apps, etc.) can help us in treatment and prevention of mental disorders.

The inclusion of Gambling and other behavioral addictions in the addictions chapter of ICD-11

S. Achab

University of Geneva, Geneva, Switzerland
doi: 10.1192/j.eurpsy.2025.74

Abstract: Background and relevance
Addictive behaviours have for the first time been included within the addiction spectrum. The transition to ICD-11 is a critical step in advancing mental health and addiction medicine.
The implementation of ICD-11 is expected to improve Health Records, facilitate Better Treatment, reduce Stigma, and enhance Public Health Surveillance.Testing the practical implications of these changes is key to ensure preparedness and smooth and effective implementation.
Methods: We conducted a comprehensive evaluation to assess the practical implications of these changes in Switzerland, determining the ease of implementation in clinical and public health settings.
Assessment consisted in:
Gathering Feedback through collecting insights from health professionals to identify potential challenges and areas for improvement.
Informing Training Needs by identifying the training requirements for health professionals to effectively use the new system.
The field testing involved multiple components: online survey, focus groups, expert reviews, key informant interviews, and a consensus conference.
Results: The testinginvolved 64 health professionals and covered diverse professional backgrounds and geographical locations). Respondents had a median of 15.25 years of experience in addiction medicine, 75% of them were Clinicians and 25% were Public Health Professionals.
Key findings of the diffrernt survey components included: High approval rates for the utility (89%), feasibility (92%) and ease of use (86%) of the ICD-11.
Strong support (90%) for the inclusion of Addictive behaviors, particularly Gaming disorder and Gambling disorder, In contrast, the broader clinical spectrum of Gaming disorder (hazardous gaming and harmful gaming) received limited support (5%).
The national consensus conference concluded that ICD-11 is mainly perceived to have a positive impact on Swiss health records, to enable better documentation of emerging health conditions, and to reduce stigma. Divergent views were represented and expressed their acceptance or reluctance towards including addictive behaviours.
Careful transition and preparedness at the national level, training health professionals along with effective communication to public audience, were reported to be essential to mitigate risks of stigma and over-pathologizing addictive behaviours.
Conclusion: The implementation of ICD-11 in Switzerland is anticipated to enhance the understanding of the societal and economic impacts of new categories such as Gaming disorder. The field-testing data collected from a wide variety of experts and care professionals underscores the need for investment in training, communication, and preparedness to ensure a smooth transition and maximize the benefits of the new classification system.

Diagnostic glide including more drug categories and more drug induced morbidities in ICD-11 may muddle our understanding of addictive disorders

J. G. Bramness

UiT The Arctic University of Norway, Tromsø, Norway
doi: 10.1192/j.eurpsy.2025.75

Abstract: In the ICD-11 the number of drug categories as "headers" for the substance related morbidity chapters has doubled. Furthermore, the ICD-11 has rationalized the number of criteria for substance dependence from six to three, but in the process in fact the threshold for receiving a diagnosis of substance dependence has been reduced substantially. Lastly, the ICD-11 has increased substantially the number of drug induced comorbidities. The former "substance induced psychosis" has now been joined by substance induced depression, anxiety disorder and even OCD for some drugs. This talk will raise some questions regarding the functionality of these changes.

Alcohol, Drugs and Addictive Behaviors in ICD-11: major changes have improved the diagnostic system

J. B. Saunders

National Centre for Youth Substance Use Research, The University of Queensland, Brisbane, Queensland 4072, Australia
doi: 10.1192/j.eurpsy.2025.76

Abstract: The latest revision of the International Classification of Diseases, ICD-11, was first issued by the World Health Organization in 2022 and a comprehensive account of mental and behavioural disorders, the Clinical Descriptions and Diagnostic Requirements (CDDR) was published in 2024. Within mental disorders is a new section "Disorders due to Substance Use and Addictive Behaviours", which sets out the diagnostic requirements for, and distinctions between, the accepted range of conditions related to psychoactive substance use and behaviours such as gambling and online (video-) gaming.
Considerable changes have been made to ICD-11 compared with its predecessor ICD-10, originally published in 1992. The process leading to ICD-11 began in 2005 and a work group for substance disorders was convened in 2010, and for addictive behaviours in 2014. Certain key considerations guided the development of the new section, which had to serve both public health and preventive and clinical diagnostic needs. These were:

- the importance for reporting a wide range of psychoactive substances for monitoring and prevention, which led to the expansion to 14 categories;
- the need on public health and also clinical grounds for having a spectrum of severity of substance use, which could be defined precisely in line with the evidence base;
- the recognition of the high-level psychometric performance of key diagnoses in ICD-10 including substance dependence; and:
- compatibility with the available data on the neurobiology and cognitive processes underlying addictive disorders.

Four central substance use diagnoses feature in ICD-11. They are, in order of severity, (i) hazardous substance use, (ii) episode of harmful use, (iii) harmful (pattern of) substance use, and (iv) substance dependence. When there is any form of unhealthy use, one of these four conditions should be diagnosed. In addition, there are many substance-induced disorders, including intoxication, withdrawal, substance-induced delirium, substance-induced mental disorders, and substance-induced neurocognitive disorders. In separate sections are the physical disorders related to substance use. There are currently two diagnoses available for specific behavioural conditions, namely gambling disorder and gaming disorder, together with the health risk factors of hazardous gambling and hazardous gaming. The presentation will include some of the empirical data that support the election of these diagnoses which form the basis for monitoring and healthcare provision in WHO (UN) member countries.

No Health Without Brain Health & the Brain Health Mission: Raising Awareness & Putting the Brain on the Top of the Policy Agenda

S. Dickson and The European Brain Council

The University of Gothenburg, Gothenburg, Sweden
doi: 10.1192/j.eurpsy.2025.78

Abstract: Brain health impacts everyone, in Europe and beyond. Whether it is the continued quest for cures and treatment for those living with brain conditions or the protection and fostering of healthy brains for our future generations, the challenges are unprecedented. To elevate brain health on the national, EU, and international policy agendas while making the most of existing initiatives, the European Brain Council (EBC) kicked off the No Health Without Brain Health campaign in the European Parliament during the 2024 Brain Awareness Week ahead of the 2024 European Elections.

This campaign is structured around two priority policy asks: the creation of a European Parliament Intergroup on Brain Health and Research and increased support to the creation of EU and National Brain plans. One year after the official kick-off, the campaign demonstrated that, when united, the brain community can reach a significant number of policymakers and make its voice heard to drive tangible policy changes.
The presentation "No Health Without Brain Health: Prioritising Brain Health in the European Union to Leave No One Behind" in this joint workshop will showcase success stories, address challenges and share good practices in EU-wide brain health initiatives. It will highlight the importance of collaboration and breaking down silos in preparing for the brain-healthy transition of our societies. Additionally, it will address the burden of brain disorders, neurological and mental alike, in a comprehensive and collaborative manner.

Sleep and brain, physical and societal health

E. Pajediene

Neurology Department, Lithuanian University of Health Sciences, Kaunas, Lithuania
doi: 10.1192/j.eurpsy.2025.79

Abstract: Sleep is essential for physical, brain (including mental) and societal health. Sleep-wake disorders are confirmed as independent risk factors and/or modulators of several neurological (such as stroke, dementia, and parkinsonism), psychiatric (depression) and other (arterial hypertension, diabetes, oncological) disorders. According to the Cost Of Illness in Neurology in Europe (COIN-EU) Study, 1.7 trillion euros cost is estimated for neurological disorders, of which 25.45% is dedicated for sleep disorders. In this talk both the socioeconomic burden of sleep disorders, and possible sleep-based interventions for improving brain and physical health, will be discussed.

The Sleep Revolution – a model for other disease assessment and follow-up

E. S. Arnardóttir[1,2]

[1]Reykjavik University, Reykjavik, Iceland and [2]European Sleep Research Society, Regensburg, Germany
doi: 10.1192/j.eurpsy.2025.80

Abstract: In this talk, Dr. Arnardottir will summarize the main findings of the SLEEP REVOLUTION, an EU Horizon 2020 Research and Innovation Programme no. 965417. The project is an inter-disciplinary and international research and development project with 39 partner institutions and companies in Europe and Australia. SLEEP REVOLUTION aims to introduce an approach based on machine learning to assess sleep apnea severity and treatment needs as well as the use of digital health technology to measure sleep and health (app, cognitive testing, consumer sleep technology and clinically validated sleep technology for home use). Through these technological solutions , the project brings together researchers, patients and healthcare professionals to provide beyond the current state-of-the-art diagnosis and optimal treatment for sleep disorders. The approach of this project can be used as a model for other disease assessment and follow-up.

Disclosure of Interest: E. Arnardóttir Consultant of: Medical Advisory Board for Philips (Feb 2022-Feb 2024) and Lille (Sept 2024), Speakers bureau of: Nox Medical, ResMed, Jazz Pharmaceuticals, Linde Healthcare, Apnimed, Wink Sleep, Vistor (Novo-Nordisk)

Sleep in Different Contexts: The Perspectives of European Psychology

J. F. Leader

European Federation of Psychologists' Assocations (EFPA), Brussels, Belgium
doi: 10.1192/j.eurpsy.2025.81

Abstract: Sleep is not something that occurs in isolation—it is embedded in a context. These contexts include biological, psychological and social factors, as well as a range of environmental considerations.
Throughout Europe psychologists engage in research and practice and collaborate with colleagues from allied professions such as psychiatry and those with lived experience on the topic of sleep.
Insights are gathered from throughout the network of the European Federation of Psychologists' Associations (EFPA). Individual examples and emergent themes are identified from a wide range of contexts including:
The role of sleep in European policy
Sleep in times of crisis
Community-oriented approaches to supporting healthy sleep patterns
The role of sleep and rest in the workplace
How concern over topics like climate change affects sleep
Competency around sleep in practitioner training and standards
The implications of digitalisation on sleep

Common pathways in the neurobiology of post-COVID conditions and of Mood Disorders

F. Benedetti[1,2]

[1]University Vita-Salute San Raffaele and [2]Division of Neuroscience, IRCCS Ospedale San Raffaele, Milan, Italy
doi: 10.1192/j.eurpsy.2025.42
Abstract: Mood disorders (MD) have been consistently associated with alterations in the immune system. Evidence suggests a condition of systemic low-grade inflammation with abnormally

decreased adaptive, increased innate immunity, and with higher levels of circulating cytokines, higher macrophage/monocyte inflammatory activation patterns, and higher neutrophils to lymphocyte counts. A dynamic pattern of premature immunosenescence and partial T cell defect starting early in adolescence, involving a reduction of naïve T cells and an expansion of memory and senescent T cells, parallels lifetime recurrence of illness episodes, worsening outcomes and fostering chronicity. Consistent systematic reviews and meta-analyses affirm that COVID-19 survivors show persistent psychopathology and neurocognitive impairment, with clinical significant depressive psychopathology being reported in around 31% of patients. Psychopathological features are the same observed in MD, along the same gradient of severity, and including a typically melancholic cognitive vulnerability. Neurocognitive impairment could possibly separate from depression in the long term, but not in the first year after infection, and it is largely overlapping with persistent cognitive deficits described in MD. We will discuss pathogenetic mechanisms shared by both, MD and post-COVID depression, with a specific emphasis on: (i) spread disruption of white matter microstructure, reduced grey matter volumes in anterior cingulate cortex, and abnormal functional connectivity in the cortico-limbic circuitries; (ii) abnormal cell trafficking across the blood brain barrier, essential for brain maintenance and repair in healthy conditions; (iii) altered immuno-inflammatory setpoints as observed in the peripheral blood, known to parallel white and grey matter abnormalities in the brain, and recently shown to disrupt neurovascular coupling and spontaneous neural activity. We suggest that post viral depression provides an invaluable model illness for the study of immune-inflammatory mechanisms involved in the pathogenesis of mood disorders, to identify new targets for treatment, with the aim of restoring mental health and brain homeostasis.

The Lancet Psychiatry Commission on Transforming Mental Health Implementation Research

J. Marsh

The Lancet Psychiatry, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.43

Abstract: Effective approaches exist to prevent and treat mental illness and to promote mental health but most people who could benefit from evidence-based interventions (policies, programmes, and individual-level practices or services) do not receive them. Too often, research produces interventions and implementation strategies that are difficult to scale owing to misalignment with the political, cultural, policy, system, community, provider, and individual realities of real-world settings. The *Lancet Psychiatry* Commission on Transforming Mental Health Implementation Research considers strategies for changing how research is done to produce more actionable evidence. It examines how to integrate research and real-world implementation; centre equity in mental health intervention and implementation research; apply a complexity science lens to mental health research; expand designs beyond the randomised clinical trial; and value transdisciplinarity across endeavours. Most mental health implementation research has been done in high-income countries but the Commission's recommendations incorporate research from low-income and middle-income countries and call for strategies to expand mental health implementation research globally.

Implementation of psychosocial treatments – who's choice and who's recovery?

T. Wykes

Psychology, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.44

Abstract: Psychosocial interventions play a role in recovery and in the patient's journey. Recovery is individual and so needs individual responses from the mental health services with individual goals set. Different interventions will be useful at different stages and, of course, they only "work" for some people. Three main strategies are often referred to – reducing symptoms, reducing barriers to recovery, and extending and maintaining recovery to achieve some stable and acceptable (to the patient) optimal level of functioning. Psychosocial intervention strategies are beneficial for each of these, and they are often thought of as independent, but they are inter-related with one type of therapy leading to reductions in the need for other therapies. Even though many of these strategies are included in guidelines, the process of considering which one to start with is a choice. We need to work out how that choice is made.

Cannabis and psychosis: from the population attributable fraction to the importance of gender differences

C. Hjorthøj[1,2]

[1]Copenhagen Research Center for Mental Health - CORE and [2]Department of Public Health, University of Copenhagen, Copenhagen, Denmark
doi: 10.1192/j.eurpsy.2025.45

Abstract: I will present data from a range of Danish studies on both cannabis-induced psychosis and Danish epidemiological studies on the association between cannabis and psychotic disorders such as schizophrenia. A deeper understanding of these associations is important. If the consistent association that we have observed for many decades is indeed causal, then cannabis is perhaps the single most important preventable risk factor for schizophrenia that we have identified to date. The development over time of the

population attributable risk fraction, gender differences, and other novel areas will be covered in the presentation.

Disclosure of Interest: None Declared

CRS005

Incidence, mortality, and the importance of drug therapy in cannabis-induced psychosis

H. Taipale

Department of Clinical Neuroscience, Karolisnka Institutet, Stockholm, Sweden
doi: 10.1192/j.eurpsy.2025.46

Abstract: Introduction
Cannabis-induced psychosis (CIP) is often assumed to resolve with sustained abstinence, although recent studies report adverse long-term outcomes, such as a high risk of diagnostic transition to schizophrenia. Cannabis is also known to increase relapse rate in individuals with psychotic disorders in general, and there is a lack of knowledge on optimal treatment of this patient group.
Objectives: In this presentation, data on incidence and mortality associated with CIP, and real-world effectiveness of antipsychotics in relapse prevention in persons with CIP will be presented.
Methods: Nationwide Scandinavian registers were utilized to identify persons with first-time CIP (ICD-10 F12.5) during the years 2000-2021. Incidence and mortality of CIP were investigated with Danish, Norwegian and Swedish register-based data, and antipsychotic use with Swedish data. Annual incidence rates of CIP per 100 000 persons were calculated. For mortality study, incident cases of CIP were matched by age- and gender with comparison persons without substance-induced psychosis and hazard ratios (HRs) were calculated for all-cause and cause-specific mortality. Association between use of specific antipsychotics (oral vs. long-acting injectable, LAI, forms) and risk of hospitalization due to any psychosis relapse was investigated in within-individual design where each person acted as his/her own control to minimize selection bias, analyzed with stratified Cox models.
Results: The incidence rate of CIP increased in time in all Scandinavian countries and was the highest in Denmark throughout the study years (rate in 2016 5.6, vs. 3.0 in Norway and 2.7 in Sweden). CIP was associated with an increased risk of mortality, risk estimates (HRs) ranging from 6.6 in Denmark, to 7.6 in Sweden, and 9.0 in Norway, compared with general population controls. In within-individual models, antipsychotic use was associated with a decreased risk of hospitalization due to psychosis relapse, with an adjusted HR of 0.75 (95% Confidence Interval 0.67-0.84), compared with time periods when the same individuals did not use antipsychotics.
Conclusions: Incidence of cannabis-induced psychosis is increasing in Scandinavian countries, and it is associated with significant mortality risk. Antipsychotics are effective treatments in preventing psychosis relapses also in individuals with CIP.

First-episode psychosis with comorbid cannabis use disorder: relapse prevention, prognosis, and mortality

S. Niemelä[1,2*], Alexander Denissoff, Pihla Sassi, Antti Mustonen, Ellenor Mittendorfer-Rutz, Jari Tiihonen and Heidi Taipale

[1]Clinical Institute (Psychiatry), University of Turku and [2]Addiction Psychiatry Unit, Turku University Hospital, Turku, Finland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.47

Abstract: Introduction: Problematic cannabis use is prevalent among individuals with first-episode psychosis (FEP), with 35.6% meeting criteria for comorbid cannabis use disorder (CUD) (1). Cannabis use is associated with poorer FEP outcomes, including higher psychosis relapse risk (2). However, evidence on effective pharmacological treatments and long-term outcomes for FEP +CUD remains limited.
Objectives: To evaluate outcomes of FEP with comorbid CUD and assess the real-world effectiveness of antipsychotic treatments in this population.
Methods: This study analyzed a Swedish nationwide cohort using longitudinal register data (2006–2021). The sample included 1,820 patients with FEP+CUD (84.7% male, mean age 26.8 years). Outcomes included hospitalizations for psychotic relapse, any psychiatric disorder, or substance use disorder (SUD). Associations between antipsychotic use and outcomes were assessed using within-individual Cox regression models. Mortality rates were compared across FEP+CUD (n=2,154, mean age 25.0 years), cannabis-induced psychosis (CIP, n=1,263, mean age 25.0), and FEP without SUD (n=17,589, mean age 27.4), adjusting for age, sex, education, other SUDs, and disability pension status.
Results: Over a mean follow-up of 6.13 years, 76% of participants were hospitalized for psychiatric diagnoses, 63% for SUD, and 61% for psychotic relapse. Antipsychotic use was associated with a 33% reduction in psychotic relapse risk. Clozapine and long-acting injectable (LAI) formulations of risperidone, aripiprazole, and paliperidone showed the greatest efficacy in relapse prevention. Clozapine reduced SUD-related hospitalizations by 86%. Within 10 years, 7.8% of FEP+CUD and 5.2% of CIP patients died, compared to 3.4% of FEP without SUD (adjusted odds ratio [aOR] 2.61, 95% CI 2.19–3.13, and aOR 1.67, 95% CI 1.28–2.17). Suicide was the leading cause of death in all groups, with higher rates in FEP +CUD (aOR 1.94, 95% CI 1.49–2.52) and CIP (aOR 1.70, 95% CI 1.21–2.37) compared to FEP without SUD.
Conclusions: Clozapine and LAI formulations of second-generation antipsychotics (excluding olanzapine) or oral aripiprazole effectively prevent hospitalizations in FEP+CUD. Targeted efforts are needed to reduce premature mortality, particularly from suicide, in FEP patients with comorbid cannabis use disorder or cannabis-induced psychosis.

CRS007

The transition from cannabis induced psychosis to primary psychosis: factors that question the validity of the diagnosis "cannabis-induced psychosis"

E. Rognli

Department of Mental Health and Addiction, Oslo University Hospital, Oslo, Norway
doi: 10.1192/j.eurpsy.2025.48

Abstract: Background: Substance-induced psychosis is an acute psychotic condition occurring after substance use, where the psychotic symptoms are alleviated with abstinence. Some of those diagnosed with substance-induced psychosis later develop schizophrenia, and this transition occurs most often for psychosis induced by cannabis. This talk will present results from a register-based study investigating transition rates. The results will be discussed together with other factors that together question the validity of the diagnostic entity of "cannabis-induced psychosis" Method: In our study, we used data from National Patient Register in Norway from 2010 to 2015 to estimate the cumulative hazard for transition from any substance-induced psychosis (F1x.5) and cannabis-induced psychosis (F12.5) to schizophrenia spectrum disorder (F20, F22 and F23). Results: The six-year cumulative hazard for transition from substance-induced psychosis to schizophrenia was 27.6% (25.6-29.7) for any SIP, and highest for those with cannabis-induced psychosis, 36% (95% CI 31.4-41.0). Conclusion: Cannabis-induced psychosis constitutes a significant risk for later schizophrenia. This raises a question of whether the initial diagnosis of CIP was correct, or whether these may have been cases of a development of primary psychosis concealed by cannabis use. Further, the term "cannabis-induced psychosis" places a major explanatory emphasis on the substance use, ignoring other potential contributing factors such as vulnerability including genetic disposition for psychosis.

Depression in an intercultural psychotherapeutic context

E. Sönmez Güngör

Psychiatry, Erenköy Mental Health and Neurological Diseases Training and Research Hospital, Istanbul, Türkiye
doi: 10.1192/j.eurpsy.2025.49

Abstract: Depression is widespread globally and is expected to be the leading cause of disability by 2030, according to the Global Burden of Disease study. Psychosocial factors, such as gender, life events, and migration experiences, increase the risk of depression, with migrants and asylum seekers showing particularly high depression rates. However, cultural differences and social background of individuals are often not adequately addressed in medical settings, which lead to misdiagnoses and mismanagement. Language and cultural barriers may complicate communication of subjective experiences, which consitute a critical part of the expression of symptomatology in depression. Depressed patients may have challenges in verbal expression of their symptoms and distress may be communicated through somatic symptoms, or what might be called as "organ language" or "somatic idiom", especially in the context of migration. Indeed, somatization is closely linked to the experience of migration stress and can be a form of cultural adaptation. Moreover, the degree of somatization in migrants is found to be related to their level of integration into the host culture. Therefore, the diagnosis and management of depression in the intercultural context can be challenging, as somatic complaints may obscure the recognition of underlying psychological distress. This can delay the seeking of psychiatric help, as patients are often reluctant to attribute their symptoms to psychological causes. Fear of stigma, or perceiving the patient as overly-dependent or attention-seeking might hinder processes of treatment and care. Existing treatment modalities with highest level of evidence, such as CBT, should be culturally adapted. Cultural adaptations involve modifying language, metaphors, and treatment goals to resonate with the patient's cultural context. While there is some evidence on the positive impact of culturally-adapted interventions including CBT, more research is needed to refine these approaches and address gaps in the literature. Psychotherapy in the intercultural context requires both cultural competence and time for dialogue.

Intercultural psychotherapy - needs and challenges

H. Siller

EIWH, Dun Laoghaire, Ireland
doi: 10.1192/j.eurpsy.2025.50

Abstract: Intercultural psychotherapy aims at an understanding of and translating between cultural differences which may be experienced between the psychotherapist and the client. This is especially important when considering that due to crisis, conflict and war, but also due to globalisation and increased mobility, an increased number of clients with a migration background seek to undergo psychotherapy. In this presentation, current literature on needs and challenges of intercultural psychotherapy is discussed with regard to an intersectionality framework and more specifically in the context of power and privileges. These frameworks provide a useful understanding of cultural competency and sensitivity in intercultural psychotherapy.

Cultural and migration-related aspects of trauma-related disorders

M. Schouler-Ocak

Psychiatry and Psychotherapy, Charité - Universitätsmedizin Berlin, Berlin, Germany
doi: 10.1192/j.eurpsy.2025.51

Abstract: Culture fundamentally influences human thinking, feeling and behaviour. The integration of cultural contexts into psychotherapeutic treatment is therefore essential, especially in light of the increasing diversity of our society. In addition, psychological stress following experiences of migration or flight requires special treatment expertise. Thus, intercultural psychotherapy is an essential approach in addressing mental health issues across diverse populations.
Life-threatening events, to which we feel helpless and at the mercy of, can inflict severe psychological trauma on us. If the event is too aversive, too horrific, and therefore cannot be autobiographically interwoven, fragments of memory are created that are not modified over time - like ordinary memories - but remain rigid, as if 'frozen'. They are activated by triggers reminiscent of the original situation and then reappear, e.g. in the form of flashbacks. The high number of people with migration and refugee backgrounds with trauma-induced secondary disorders calls for culturally sensitive, trauma-focussed psychotherapies to close the enormous gap in care. Numerous psychotherapies are available for the treatment of trauma-related disorders, some of them have yet to be evaluated - or modified for the treatment of traumatised persons in the context of migration and flight in the case of those that have already been well evaluated. This presentation will give an overview on cultural and migration-related aspects of trauma-related disorders.

AVATAR therapy: results of a phase 2/3 Clinical Trial of a blended digital therapy for auditory verbal hallucinations

T. K. J. Craig on behalf of AVATAR Therapy team and AVATAR therapy

Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.52

Abstract: Avatar therapy is a digital therapy supported by a therapist in which voice hearers dialogue with a digital embodiment of their most distressing voice. Our previous randomised controlled trial of AVATAR therapy showed 6 sessions had a superior and substantial reduction in the severity of voices compared to that achieved by supportive counselling. Limitations included that the study was carried out in a single site, and six sessions limited what might be achieved by an extended approach to include a greater focus on individual biographical characteristics that had a bearing on the voice hearing experience . In the latest AVATR2 trial, we aimed to replicate these early results and deliver therapy by a wider workforce across several centres in the UK. We also tested the effectiveness of two forms of therapy -AVATAR Brief 6 sessions (AV-BRF) and AVATAR-Extended 12 sessions (AV-EXT). In this presentation I report the results of this clinical trial. We hypothesised that both forms of therapy alongside treatment as usual would be effective and superior to treatment as usual alone in reducing voice related distress (the primary outcome) at 16 and 28 weeks follow up. We found that both treatmetns did indeed reduce distress at 16 weeks and that this reduction was maintained at 28 weeks though was no longer statistically significant in compoariuson to treatment as usual at this point. The frequency of voices also reduced at both time points for AV-EXT that also achieved several other important outcomes in cluding enhanced wellbeing and reductions in delusional beliefs associated with the voice. There were no related serious adverse events. A health economic analysis was also carried out that also supports AV-EXT The next phase of the development of AVATAR therapy towards release for routine use is briefly described.

Feasibility, acceptability and outcomes of blended care with smartphone-based ecological momentary assessment and intervention in schizophrenia spectrum disorders: A pilot single-arm trial

K. Böge

Charite, Berlin, Germany
doi: 10.1192/j.eurpsy.2025.53

Abstract: Delusions are one of the core symptoms of schizophrenia spectrum disorders (SSD). Traditional Cognitive Behavioral Therapy (CBT) approaches are less effective for delusions, require significant resources, and specialized staff training. Symptom-specific therapy approaches, which target factors involved in the development and maintenance of psychotic symptoms, provide a valid alternative. Digital technologies, such as ecological momentary assessment (EMA) and ecological momentary intervention (EMI), are gaining attention in mental health, providing enhanced assessment and intervention opportunities. The present single-arm trial aimed to investigate the feasibility, acceptability, and preliminary outcomes of a smartphone-based blended EMA/I psychological therapy approach - DICE - focusing on improving coping strategies for delusions in SSD. In total, $N = 10$ participants received four face-to-face therapy sessions alongside German university-level treatment-as-usual over an intervention period of four to six weeks. Feasibility was assessed by completion rates of the EMA/I questionnaires, use of the application between sessions and recruitment rates. Acceptability was assessed by a satisfaction questionnaire, open feedback, and analysis of adverse effects. Clinical outcomes included self-

rated and rater-based intensity and distress of delusions and comorbid symptoms at pre- and post-intervention. Findings supported the feasibility and acceptability of the DICE intervention, with high retention (10/13 participants; 77%) and completion rates for the EMA- (59%) and EMI-questionnaires (72%), as well as a high protocol adherence (90-97%), exceeding all predefined benchmarks. Open feedback indicated good satisfaction, with all participants using the application between sessions, reflecting a high engagement level. Clinical outcomes displayed relevant changes in ameliorating the intensity of delusions when being measured by the Psychotic Symptom Rating Scales as well as by the Green Paranoid Thought Scale, and self-rated improvements in distress and depressive symptoms. Changes in the intensity and distress of delusions might be explained by improved coping behaviour. Further research with control conditions is needed to validate findings and analyze the efficacy as well as mechanisms of actions of the DICE intervention in a fully powered trial.

Effectiveness and efficiency of Virtual Reality cognitive behavioural therapy for paranoid delusions - results from a randomized clinical trial

W. Veling

Department of Psychiatry, University Medical Center Groningen, Groningen, Netherlands
doi: 10.1192/j.eurpsy.2025.54

Abstract: Background: Cognitive behaviour therapy is the main evidence-based psychological treatment for paranoid ideations in patients with psychotic disorders. Virtual reality may improve psychological treatment, because it facilitates behaviour interventions aimed at reducing avoidance and dropping safety behaviours. We investigated the effects of virtual-reality-based cognitive behaviour therapy for paranoid ideations (VR-CBTp) compared to standard CBTp.
Methods: We performed a pragmatic single-blind, randomised clinical trial in seven mental health centres in the Netherlands and Belgium. Eligible patients had a psychotic spectrum disorder and experienced paranoid ideations. Both interventions consisted of 16 sessions maximum. Treatment could be completed early when all goals had been achieved. The primary outcome was momentary paranoia, measured with the experience sampling method (ESM). Secondary outcomes included other measures of paranoid ideations, safety behaviour, social anxiety, depression, worry and self-esteem.
Findings: 103 participants were enrolled and 98 randomised to VR-CBTp (n=48) or CBTp (n=50). At post-treatment, VR-CBTp had significantly stronger effects than standard CBTp at post-treatment on momentary paranoia (interaction effect b=-0·3, 95% CI -8·4 to 7·8, n=81, p=0·04, effect size 0·62), safety behaviour, depressive symptoms and self-esteem, of which the difference in effects on self-esteem and social interaction anxiety remained at follow-up. Completers on average received 12·4 (VR-CBTp) and 15·0 (CBTp) sessions. Limited ESM compliance resulted in 43% data loss at post-treatment and 49% at follow-up.
Interpretation: CBTp and VR-CBTp are both efficacious treatments for paranoid ideations, but VR-CBTp may be somewhat more effective and more efficient than CBTp.

Findings from RCT's on virtual reality-based interventions for auditory hallucinations and paranoia

L. Birkedal Glenthøj[1,2*] and M. Nordentoft[3,4]

[1]VIRTU Research Group, Mental Health Center Copenhagen, Copenhagen University Hospital; [2]Psychology; [3]Clinical Medicine, University of Copenhagen and [4]Copenhagen Research Center on Mental Health, Copenhagen, Denmark
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.55

Abstract: Introduction: Virtual reality (VR) has the potential to enhance current psychotherapies for psychotic symptoms by simulating virtual environments that evoke responses reflective of real-world scenarios.
Objective: This study aimed to evaluate the effectiveness of VR-based psychotherapeutic interventions through findings from two large-scale randomized clinical trials—CHALLENGE and Face Your Fears—that targeted auditory hallucinations (AH) and paranoia, respectively, in individuals with schizophrenia spectrum disorders (SSD).
Method: The CHALLENGE and Face Your Fears trials were randomized, assessor-blinded, parallel-group superiority trials that enrolled 270 and 254 patients with SSD, respectively. In the CHALLENGE trial, participants were randomized to 7 sessions of Challenge-VR therapy (Challenge-VRT) or treatment-as-usual (TAU). In Face Your Fears, participants received either 10 sessions of VR-CBT or standard CBT.
Results: Linear mixed-model analyses on primary and secondary outcomes in both trials revealed that in the CHALLENGE Trial, Challenge-VRT significantly reduced AH symptom severity, as measured by the Psychotic Symptoms Rating Scales (PSYRATS-AH total, adjusted mean difference: -2.26, 95% CI: -4.26 to -0.25, p = 0.03) and frequency (PSYRATS-Frequency, adjusted mean difference: -0.84, 95% CI: -1.53 to -0.14, p = 0.02) at treatment cessation. Face Your Fears Trial: No significant differences were observed between groups on the primary outcome at endpoint (adjusted mean difference: 1.12, 95% CI: -1.75 to 3.99; Cohen's d = 0.10; p = 0.44). However, both groups demonstrated large within-group improvements (VR-CBT: Cohen's d = 0.88; standard CBT: Cohen's d = 0.87). Standard CBT demonstrated superiority over VR-CBT on the secondary outcome measure emotion recognition latency overall at treatment cessation (adjusted mean difference -348.3, 95%CI: -696-6 to -0.04; Cohen's d = 0.25, p= 0.05), and on emotion recognition accuracy, sadness at 9 months follow-up (adjusted mean difference 0.85, 95% CI: 0.06 to 1.63; Cohen's d = 0.27, p= 0.03). No serious adverse events were reported in either trial.
Conclusion: Challenge-VRT appears to be a promising treatment for reducing the severity of AH in SSD, though further research is

required to optimize and extend its efficacy across broader aspects of schizophrenia. In contrast, VR-CBT did not demonstrate superiority over standard CBT for paranoia, suggesting that both treatments may offer comparable benefits. Future research should explore mediators and moderators of treatment efficacy, as well as patient preferences, to tailor interventions for maximum impact.

Time trends in public stigma

G. Schomerus* and Mental Health and Society Working Group, Leipzig University

Department of Psychiatry, Leipzig University, Leipzig, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.56

Abstract: Attitudes toward people with mental illness change. We present evidence of attitude change from different contries, with regard to different mental health conditions. While attitudes towads mental health problems in general, and towards depression, seem to soften, there is little positive change with regard to people with substance use disorders, and attitudes have even worsened towards people with schizophrenia. We discuss possible explanations for these diverging trends, and hypothesize on potential remedies.

Role of national psychiatric associations against pseudoscientific and misleading information and practices concerning mental health

K. Başar

Psychiatry, Hacettepe University, Ankara, Türkiye
doi: 10.1192/j.eurpsy.2025.57

Abstract: Since their emergence as healthcare practices with scientific backgrounds, psychiatry and psychology have been criticized and attacked in different ways. Their scientific base has often been questioned, but more generally, their applications were suggested to follow alternative motives rather than the highest benefit of the suffering individuals. The antipsychiatry movement, with decades of history, on some occasions, could be considered to play an important role in optimizing psychiatric practices. However, with the increasing societal influence of antiscientific and pseudoscientific discourses, a significant section of individuals with mental health issues experience delays in their access to appropriate care and are sometimes harmed by the practices recommended as alternatives to psychiatry or medicine in general. There has been an increase in such misleading discourses following the pandemic, probably based on the uncertainty and lack of information on the nature of the infection and prevention methods, including the vaccine. In some instances, these misleading attitudes toward psychiatry and psychiatric practices are also pioneered by medical professionals. Some medical professionals deny the need and effectiveness of psychiatric practices, and some employ or recommend methods of care despite their lack of training and experience and the questionable nature of the practices. In many countries, national psychiatric associations are considered a leading source of information concerning mental health-related issues. However, without a systematic, need- and problem-focused strategy, including publicly available and acceptable information resources, it is difficult to oppose the overflow of misleading information currently available. Laws and regulations in many countries may act as a barrier against practices with no evidence base or with evidence of harmful effects. However, there are challenges in their implementation and limitations in their scope. National psychiatric associations may need to be involved in creating and implementing such regulations.

Peptide specific antibodies to Epstein Barr Virus and Toxoplasma gondii as markers of psychiatric disorders and suicide behaviors

R. Yolken[1]* and F. B. Dickerson[2]

[1]Pediatrics, Johns Hopkins School of Medicine, Baltimore and [2]Psychology, Sheppard Pratt, Towson, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.58

Abstract: Immunoassays such as enzyme-linked immunosorbent assays (ELISAs) provide precise measurements of class-specific antibodies to infectious agents. The application of these assays to blood and cerebrospinal fluid from individuals with psychiatric disorders has supported a role for microbial agents in these conditions. However, standard immunoassays are limited by their capacity to measure antibodies to only a single or a small number of infectious agents and epitopes, restricting the ability to identify differential immune responses.

Recent technological advances now allow for comprehensive profiling of immune responses to multiple infectious agents and their specific antigenic epitopes. These methods enable the investigation of differential immune responses as potential modulators of psychiatric disease risk.

We applied two novel serological platforms to analyze immune responses in blood samples from individuals with various psychiatric disorders and suicidal behaviors, as well as healthy controls. The first method assessed antibodies to >4200 peptides derived from >80 infectious agents immobilized onto a solid-phase surface. These peptides were incubated with small blood volumes, and antibody binding was detected via secondary reactions.

Results demonstrated significant differences in immune responses to *Toxoplasma gondii* and Epstein-Barr virus (EBV) in individuals with schizophrenia and other severe psychiatric disorders. Responses to *T. gondii* were primarily directed at dense granule (GRA) proteins, with multiple GRA peptide reactivities detected even in individuals classified as "seronegative" by standard immunoassays. For EBV, differential responses were observed to ZEBRA and other latency-associated proteins. Findings were corroborated using a phage

display system, where peptides derived from viral proteins were expressed on the phage surface.
Interestingly, immune reactivity was not uniformly increased or decreased but varied depending on the specific antigen. These findings suggest that psychiatric disorder-associated immune alterations may not merely reflect pathogen exposure but also differences in immune response patterns. Further investigation of these differential responses could inform novel diagnostic, preventive, and therapeutic strategies for severe psychiatric disorders.

Viral exposure and its effects on subsequent development of a mental illness: Results from the VIRAL-MI consortium project

D. Tzur Bitan* and VIRAL-MI consortium

Community Mental Health, University of Haifa, Haifa, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.59

Abstract: Background: Infectious diseases are known to significantly increase the risk for later development of a mental disorder. Nonetheless, only few studies utilized big-data strategies to evaluate whether cumulative viral infection increases the risk of a subsequent mental illness, and whether risk and resilience factors a likely to modify theses associations. Methods: This study assessed the likelihood of mental illness development among individuals with recurrent exposure to pre-determined viruses (n = 53,416). The viral blood tests included in the analysis was based on consensus agreement of the VIRAL-MI consortium members, and was based on test validity, mandatory vaccination profiles, and the test's ability to detect acute infection. Broadly, these tests included positivity to the following viral infections: Cytomegalovirus, Epstein-Barr virus, Hepatitis, Herpes, Toxoplasma and Influenza. Data was obtained through the Clalit Health Services, the largest healthcare organization in Israel. Results: Overall, 663,231 tests were obtained from the cohort of 53,416 cases. Kaplan-Meier analyses indicated that individuals infected with more than three viruses were significantly more likely to develop a mental disorder (Log rank 14.55, p<.001). Of the investigated disorders, only anxiety disorders presented a significantly differential pattern of cumulative risk, in the same direction (Log rank 10.06, p = .007). Conclusions: Cumulative viral infections may have significant contribution to the development of a mental disorder. Limitations and integration with previous research will be discussed.

Are side effects necessary for antidepressant treatment?

S. Kasper

Department of Molecular Neuroscience, Medical University of Vienna, Vienna, Austria
doi: 10.1192/j.eurpsy.2025.84

Abstract: The recent development of the socalled "psychedelics" reminds us that unfortunately some medications which we used in psychiatry have a large burden of side effects, like the anticholinerg side effects of the older tricyclic antidepressants as well as the extrapyramidal motoric side effects of socalled typical neuroleptics. These side effects were sometimes also related to the efficacy of these medications. Interestingly, it seems that the neglection of side effects is still an unresolved issue in clinical psychopharmacology, since there are researchers and clinicians who argue that the psychedelic experience induced with psychedelics are associated with therapeutic efficacy. Furthermore, studies in this field not even mention these side effects as such and argue, when confronted with the issue, that these are necessary for the therapeutic outcome. Even more so, there are researchers and clinicians who think that these side effects allow the patients to understand their unconscious, like in the early days of psychoanalysis. However, recent preclinical animal models demonstrated antidepressant-like behavioral effects and synaptic actions that are not only linked to the serotonergic activation (mainly via the 5HT2A receptor), but also via opioid and glutamatergic pathways which share neurobiological mechanisms of network reconfiguration likely by intracellular plasticity cascades. It seems to be important from my point of view to develop antidepressant medications devoid of the side effect of psychedelic experience in order to produce a safer, non-hallucinogenic medication that has therapeutic potential for depressed patients.

What about the trip? The relationship between ketamine's acute and antidepressant effect

V. Andrashko[1,2]

[1]National Institute of Mental Health, Klecany and [2]Third Faculty of Medicine, Prague, Czech Republic
doi: 10.1192/j.eurpsy.2025.85

Abstract: Ketamine has been established as a rapid and potent antidepressant. However, despite its groundbreaking efficacy, it has several limitations, including the transient nature of its antidepressant effects following a single infusion, as well as the phenomenology of acute intoxication. This state is characterized by altered consciousness, manifesting as dissociative or psychotomimetic phenomena, along with cardiovascular changes, such as fluctuations in systolic and diastolic blood pressure.
The presentation explores whether these phenomena should be regarded as mere side effects or if they might play a role in ketamine's antidepressant mechanisms. Furthermore, it addresses

the ongoing challenge of identifying clinical and phenomenological predictors of a better antidepressant response.

Is There a Burnout Epidemic among Medical Students?

M. Di Vincenzo

Department of Psychiatry, University of Campania "Luigi Vanvitelli", Naples, Italy
doi: 10.1192/j.eurpsy.2025.86

Abstract: Medical students are persistently exposed to specific conditions that may have detrimental effects on mental health, such as stressful academic routine, demanding and heterogeneous curriculum, sense of competition and daily exposure to illness and death. Accumulating evidence highlights high levels of cynicism and emotional exhaustion among these subjects. Indeed, the prevalence of burnout syndrome in medical students may reach peaks up to 88% in some studies. Thoughts of stopping medical education, negative life events, lack of support, dissatisfaction, and poor motivation represent the main predictors of burnout in this group. Such findings highlight the need to develop prevention initiatives targeting the future generation of medical doctors. Moreover, implementation of psychosocial interventions delivered from medical schools could be helpful to improve coping strategies and resilience styles of students.

Importance of intercultural paradigm in affirmative clinical practice with LGBTIQ+ people

I. Zegura

Department for Psychotic Disorders, University Psychiatric Hospital Vrapce, Zagreb, Croatia
doi: 10.1192/j.eurpsy.2025.87

Abstract: Professionals' attitudes, cultural background, and previous experiences are relatively stable and organized features of their backgrounds. They can affect the therapeutic process and provision of health care to LGBTIQ+ clients in both directions- affirmative and oppressive. Healthy development of sexual orientation and gender identity and their integration is one obvious prerequisite for healthy psycho-sexual and psychological development. Mental health care professionals should be aware of their attitudes, and cultural background, and how they can influence the therapeutic process with and provision of health care to LGBTIQ+ clients to provide culturally sensitive and LGBTIQ+ affirmative practice.
LGBTIQ+ affirmative health care can include any single or combination of several social, psychological, behavioral, or medical interventions designed to support and affirm an individual's sexual orientation and/or gender identity.
Stigma-related stressors experienced by LGBTIQ+ people across these levels can take the form of relational trauma, and thus compound general life stressors that represent an additional risk for different stress-related outcomes including poor mental health and health-risk behaviors.
Expectations of rejection might be particularly frequent experiences among transgender and gender-diverse people. Existing data depict LGBTIQ+ populations to be at a greater risk for poor health outcomes and a plethora of risk behaviors.
Transgender and gender diverse (TGD) people most often perceive available healthcare to be of inadequate quality and potentially unsafe. However, up to now healthcare systems across Europe fail to provide equal access for TGD compared to cisgender people It has been estimated that at least 27% of TGD people in Europe fail to access TGD care. Compared to cisgender people and compared to lesbian, gay, bisexual, or intersex people, TGD people are most affected by not having access to appropriate care, and they are among those reporting the highest rates of experiencing bad health.
Access to the highest standard of LGBTIQ+ affirmative health care, including LGBTIQ+ affirmative approach within psychotherapeutic practice, that respects dignity and right of self-determination, personal, physical, and psychological integrity, autonomy, and wellbeing of LGBTIQ+ people, and that relies on evidence-based practice, clinical guidelines and standards of care should be a priority across European health care systems and psychotherapeutic modalities. Education and sensitization of medical, and mental health professionals, psychotherapists, and other health care professionals on sexuality, sexual orientations, gender identities, and diversities should be implemented as core intercultural competencies through the obligatory curriculum courses of health and mental health professionals.

LGBTIQ+ Specialty Care in USA: The Continuing Need for Specialty Clinics and Resources.

A. Ahuja and LGBTQ

Los Angeles LGBT Center, Los Angeles, United States
doi: 10.1192/j.eurpsy.2025.88

Abstract: This presentation will serve as an overview of LGBTQ+ Clinical Care in the United States and throughout the world. Using the specific example of the Los Angeles LGBT Center, Dr. Ahuja will discuss the need for an LGBTQ+-specific mental health clinic. The reasons for having specialized care are numerous, but boil down to several significant areas.
First, the LGBTQ+ community suffers from large health disparities. This often results from lack of specialized knowledge by providers and health advocates. An LGBTQ+ specific center allows for experts to exchgange and enhance information, incerased research into this population which results in better standars of care, and a chance to educate others regarding LGBTQ+ care. They can serve as a model for other clinics or any other health settings where practitioners can implement LGBTQ+-specific practices that work for them and their patients and on a scale that makes sense.

Second, there is much evidence of discrimination by healthcare providers and insurance companies regarding the LGBTQ+ community, particularly when it comes to the Transgender population. This can include rude behavior by providers, missed screenings due to not paying attention to patient anatomy or LGBTQ+ status, misgendering, harrasment, and lack of insurance coverage for procedures. An LGBTQ+ center allows for patients to have healthcare advocates who can fight for approval and ensures that patients are not harrassed for being LGBTQ+ which results in many patients forgoing necessary care. Further, screenings and patient education regarding things like Pre-Exposure Prophylaxis and Hormone Therapy are much improved as the center and its providers have the knowledge and mission to carry out large-scale educaton efforts. Finally, an LGBTQ+ center like the Los Angeles LGBT Center inevitably becomes a community hub. These centers function to not just provide medical care but also to advocate for LGBTQ+ issues, coordinate with other centers to manage population disease outbreaks, fight misinformation and disinformation with accurate research, and provide many ancillary services including housing and social community spaces.

LGBTQ+ transcultural psychiatry – the need for capacity building, specialized psychiatric services and recognizing the specific needs of LGBTIQ+ refugees in the Nordic countries

G. Mijaljica[1,2]

[1]DPS Øyane, Haukeland University Hospital, Bergen, Norway and [2]Transcultural Centre Stockholm, Stockholm, Sweden

doi: 10.1192/j.eurpsy.2025.89

Abstract: People within LGBTIQ+ are significantly more likely to suffer a mental health disorder and substance use disorder compared to heterosexual persons. Stigma, discrimination, and lack of social support are considered as some of the contributing factors to the higher incidence of psychiatric morbidity in this group. Simultaneously, the group's rights vary around the world, and example being that for example homosexuality is criminalized in many countries and sometimes punishable by death.

Even in countries where homosexuality and belonging to LGBTIQ+ community is not criminalized or is well accepted in the society; the studies show increased odds of poor mental health in this group. For example, a study conducted in Sweden, where same – sex marriage is legal, comparing suicide risk between heterosexual and same-sex married couples showed that same-sex married men had a was nearly three-fold greater suicide risk in comparison to their heterosexual counterparts. Accessible and evidence – based LGBTIQ+ affirmative psychiatric services are crucial for addressing the mental health care needs of the group. These services can be supported by well-structured and efficient training of mental health care professionals.

E-health interventions in postpartum stress: needs assessment and developmental steps towards online interventions

K. Koelkebeck[1,2*] and A. Bäuerle[3]

[1]Department of Psychiatry and Psychotherapy, LVR-University Hospital Essen, Essen; [2]Protestant Hospital of the Bethel Foundation, University Hospital for Psychiatry and Psychotherapy, Bielefeld and [3]Department of Psychosomatic Medicine and Psychotherapy, LVR-University Hospital Essen, Essen, Germany

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.90

Abstract: Postpartum stress and mental disorders have a high prevalence in the population. Postpartum depressed states, for example, potentially threaten care of and bonding with the children. Although mothers face specific needs, specialized treatment options are scarce. Online programs to inform on and treat postpartum stress and depression are, to present, not widely available, but have the potential to overcome some of the obstacles of postpartum women finding treatment.

To identify needs of this specific group, we conducted an online survey on women after childbirth, asking for acceptance of e-health programs, sociodemographic, medical and psychometric data.

In a large, anonymized online survey, 453 women have participated. We investigated 1) the acceptance of tailored e-mental health programs according to the UTAUT model in the respective women and 2) characteristics and needs of the specific populations. Based on our findings, we developed an online tool for stress reduction after child-birth based on relevant topics indicated by and data from the literature on specific needs of post-partum women.

In this talk, motivation for this project, research results and ongoing research will be highlighted and discussed.

BREF: the value of a short early intervention for informal carers and families for reducing stress and burden of care

E. Scanferla[1,2*] and R. Rey[3,4,5]

[1]CRPMS (EP), Université de Paris; [2]GHU Paris psychiatrie et neurosciences, Paris; [3]Centre Lyonnais des Aidants en Psychiatrie (CLAP), Le Vinatier-Psychiatrie Universitaire Lyon Métropole, Bron; [4]Fondation FondaMental, Créteil and [5]U1028/UMR5292, INSERM/CNRS, Lyon, France
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.91

Abstract: Introduction: Informal caregivers are essential in supporting individuals facing mental health challenges, yet the demanding nature of their role can lead to significant distress and long-term psychological strain. International guidelines consistently highlight the critical importance of early caregiver support and identify psychoeducation for caregivers as one of the most effective interventions to support them. However, psychoeducational programmes for caregivers remain significantly underutilised. To address this pressing gap in mental health support, Rey et al. (2020), in collaboration with Unafam, the French national family association, developed the BREF programme. This innovative psychoeducational intervention is designed to provide early and systematic support for caregivers of people with severe mental disorders.
Objectives: This study investigated the impact of the BREF programme, focusing on its potential to mitigate depressive symptoms and alleviate the psychological burden experienced by caregivers.
Methods: This study used a single-group pre-post design. It included family caregivers who participated in the BREF programme from November 2020 to March 2022. Changes in caregiver depressive symptoms (CES-D) and burden (ZBI) measured pre-, post- and 3 months after intervention. Caregivers' satisfaction and perceived usefulness were also assessed.
Results: Data from 206 family caregivers were analysed. The depression and burden scores significantly decreased immediately after the intervention ($p<0.001$) and at the 3-month follow-up ($p<0.05$). Additionally, 98% of participants reported being satisfied to very satisfied, 95% of them deemed it very to extremely useful.
Conclusions: The BREF programme demonstrated significant benefits, notably reducing caregivers' depressive symptoms and burden. Designed for early systematic implementation this standardized, time- and resource- efficient intervention, offers à promising foundation for a structured and graduated support pathway for caregivers.

The use of apps in public mental health: assessing needs and re-developing programs for integration into society

V. J. J. A. Buwalda

Psychiatry, GGD, Amsterdam, Netherlands
doi: 10.1192/j.eurpsy.2025.92

Abstract: In the last decennium there is an explosion of medical devices to help patients in their fight against their psychiatric disorder and if possible to take more control and responsibilities over their own lives. In our research on measurement instruments it was doubted that patients were able to use computers and apps. Happell, 2009, addressed that psychiatric patients were very interested in using apps and also were positive being partners in the development of apps that could enhance their quality of life. Their attitude towards apps in clinical practice was more positive than their clinicians who were afraid of being judged on their performance and are more hesitant (Buwalda, et al., 2015). 10-15 years later millions of patients and clinicians are using applications and other medical devices to enlighten their lives.
But what about the most vulnerable citizens, our patients, in the cities in the context of urbanisation. In Amsterdam the public mental health services developed the self-sufficiency matrix (SSM) to gain insight in the peoples individual possibilities. A measure that insights the adaptation to the complex city life and how they can take care of themselves in this ever changing world. How do they feel about using apps or their professionals in daily clinical practice?
This presentation is about the history of the development of a mental health app for psychiatric patients in the city to be used by the professionals. Through a small pilot the presenter will a show the process of development of the SSM-app that gives insight in the wellbeing of the most vulnerable and their needs. We will also discuss the challenges and user-friendliness of the SSM- app in our PMH to make our work more digital proof.

Patient perspectives on the development of a prescription opioid use disorder

L. E. M. Davies[1*] and A. Schellekens[2,3]

[1]Utrecht University, Utrecht; [2]Department of Psychiatry, Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Center and [3]Nijmegen Institute for Scientist Practitioners in Addiction, Nijmegen, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.93

Abstract:
Introduction: In the past decade, prescription opioid use increased exponentially and concomitantly prescription opioid use disorders (OUD) are becoming more common. While substantial research has identified clinical risk factors, little attention has been paid to the lived experiences that contribute to the development of OUD.
Objectives: This study aimed to explore and document patients' experiences on how they developed a prescription OUD.
Methods: We conducted in-depth, semi-structured interviews with 25 adults with chronic non-cancer pain currently undergoing treatment for prescription OUD. The interviews explored their experiences with long-term opioid use, attitudes toward opioids, and access to prescriptions. Transcripts were analysed using directed content analysis to identify recurring themes.

Results: Participants identified three key themes influencing the development of OUD: (1) experiences driving initiation, (2) experiences driving continuation, and (3) experiences with prescription OUD. Beyond pain management, factors such as patient-provider communication, care coordination, provider vigilance, and environmental support significantly shaped opioid use patterns.Participants cited a lack of guidance during both initial and long-term opioid use, easy access to prescriptions, and insufficient monitoring as major contributors to OUD. Poorly controlled pain and high levels of stress were also highlighted as critical drivers of continued opioid use.
Conclusions: Patients described a distinctive pathway to prescription OUD, contrasting with other substance use disorders, with negative reinforcement playing a particularly prominent role in the early stages of opioid use. Their perspectives reveal critical gaps in guidance and monitoring during opioid therapy, highlighting opportunities for intervention and improvement.
This talk will explore how these insights can inform prevention strategies, improve care coordination, and support better outcomes for patients at risk of OUD.

Prevention of prescription opioid use disorder

F. Fonseca[1,2*] and RD24/0003/0001 co-funded by Instituto de Salud Carlos III (ISCIII) and by the European Union

[1]Mental Health Institute, Hospital del Mar Research Institute and [2]Medicine and Life Sciences Department, Universitat Pompeu Fabra, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.94

Abstract: It is important to address the prevention and early detection of opioid addiction with a comprehensive approach. The collaboration and early attention are essential to mitigate the risks associated with opioid misuse. In this session we will review the myths associated with high risk of opioid addiction and how to address when it has been developed.
Some key strategies could be: Provide accurate and understandable information about the risks associated with opioid use, as well as the early signs of addiction. Consider alternative options for pain management, such as physical therapies, exercise, and medications non-opioids, before prescribing opioids. It is important balance pain relief with control of possible addiction risks. The appropriate and controlled indication of opioids is of vital importance to prevent and detect inappropriate use. Prescribe the lowest dose and duration shortest possible. It is important to visit frequent monitoring to detect signs of misuse and/or addiction.

Tapering in patients with chronic pain and prescription opioid use

A. Schellekens

Psychiatry, Radboudumc, Nijmegen, Netherlands
doi: 10.1192/j.eurpsy.2025.96

Abstract: Opioid use disorder in patients with chronic pain poses a specific clincal challenge. Tapering opioids can initially increase pain, while continuing opioids is associated with tolerance and opioid induced hyperalgesia, resulting in inadequate analgesia. In the long run tapering of opioids or rotation to long-acting alternatives, such as buprenoprphine or methadone, have been associated with less pain and better qualtity of life. In this presentation, evidence for various tapering and rotation strategies will be presented, as well as the possiblities for integrated pain management and addiction care. After this session you will know how to prepare your patient with presciroption opioid use disorder and chronic pain for tapering of opioids, how to support your patient with tapering, including the pace of tapering and the use of supproting pharmacological and non-pharmacoligcal interventions. Finally, it will be discussed who is more likely to benefit from rotation to long-acting opioids, and why some patients might be better of without opioid tapering.

Determinants of Mental Health in Europe

J. D. Lopez Moriñigo

Lundbeck España, S.A., Barcelona, Spain
doi: 10.1192/j.eurpsy.2025.97

Abstract: Introduction This presentation will provide an up-to-date cross-national comparison of the individual, environmental and socioeconomic determinants of the European population mental health (MH). Methods The European House & Ambrosetti-funded 2023 Headway Mental Health Index 3.0 initiative collected data on 19 Key Performance Indicators (KPIs) in individual (e.g., smoking), environmental (e.g., air pollution) and socioeconomic (e.g., poor housing conditions) determinants of MH for the European Union 27 countries and the UK. KPIs scores were standardised in a 1-10 Likert Scale (1: worst performance; 10: best performance), thus allowing between-country comparisons of the relative performance. Unadjusted bivariate correlations between KPIs scores were run. Results Finland (8.0), Sweden and Estonia (7.5) had the lowest MH risk, while France (3.1) and Romania (2.8) had the highest MH risk. Smoking ($r=-0.43$, $p=.021$), alcohol use ($r=0.57$, $p=.002$), daylight hours ($r=0.74$, $p<.001$), ecoanxiety ($r=-0.51$, $p=.005$), air pollution ($r=-0.46$, $p=.015$), commuting time ($r=0.42$, $p=.026$) and Fragile State Index ($r=-0.44$, $p=.018$) correlated with overall MH status, thus emerging as common determinants of MH across the board. Conclusions The determinants of MH varied across European countries, although the correlation between determinants-based MH risk and MH status was relatively weak, including 'low-risk, poor MH status' and 'high-risk, good MH status' countries. Further non-tested determinants of MH and/or between-country differences in their responsiveness to the population MH needs may explain this discrepancy. These results may inform future evidence-based public MH policymaking and universal preventive strategies in Europe.

Responsiveness to Mental Health Needs across European countries

C. Arango

Hospital General Universitario Gregorio Marañon, UCM, CIBERSAM, Madrid, Spain
doi: 10.1192/j.eurpsy.2025.98

Abstract: This study evaluated European countries' responsiveness to mental health (MH) needs by analyzing key performance indicators (KPIs) across healthcare, workplaces, schools, and society. Data from the 2023 Headway Initiative included 15 KPIs related to healthcare responsiveness—such as workforce availability, facilities, quality of care, and MH expenditure—and 14 KPIs assessing responsiveness in workplaces, schools, and society. KPI scores were standardized on a 1-10 Likert scale, with higher scores indicating better performance. Bivariate correlations examined associations between responsiveness and overall MH status. Sweden (10.0), Denmark (8.8), and Finland (8.3) demonstrated the highest responsiveness in healthcare, whereas Romania (1.0), Slovakia (1.1), and Latvia (1.2) ranked lowest. In non-healthcare domains, Germany (10.0), France (9.1), and Denmark (9.1) were the most responsive, while Greece and Slovakia (1.0) exhibited the poorest performance. These findings highlight significant disparities in MH support across Europe and emphasize the need for policies that address inequalities and bridge treatment gaps. Future efforts should focus on balancing MH status improvements with sustained investment in MH responsiveness.

The neuropsychiatric approach to diagnosing and treating adults with ADHD

S. Lodhi

Department of Psychiatry, Harvard Medical School, Boston, United States
doi: 10.1192/j.eurpsy.2025.100

Abstract: Background: Attention-deficit/hyperactivity disorder (ADHD) in adults often presents with nonspecific symptoms that can be obscured by years of compensatory mechanisms and comorbid conditions. Traditional diagnostic approaches may fall short in capturing the nuanced presentation of ADHD in previously undiagnosed adults, leading to potential misdiagnosis or delayed treatment. This talk presents a comprehensive clinical framework for evaluating adult ADHD that integrates structured assessment protocols with thorough clinical investigation.
Methods: Our diagnostic model employs a multi-stage evaluation process that includes: (1) comprehensive pre-interview rating scales, (2) in-depth clinical interviews focusing on lifetime symptom presentation and functional impact, (3) systematic gathering of collateral information, and (4) administration of validated assessment instruments with embedded validity scales. The evaluation protocol emphasizes the assessment of executive function, emotional regulation, and adaptive behaviors developed throughout adulthood.
Discussion: This approach represents a significant advancement in adult ADHD diagnosis by incorporating validated assessment tools with thorough clinical investigation. The model's emphasis on lifetime symptom patterns, adaptive behaviors, and compensatory mechanisms provides crucial insights into how ADHD manifests in adults who have developed various coping strategies throughout their lives. Furthermore, the integration of multiple data sources with patient insights facilitates better treatment engagement and outcomes.
Conclusion: The proposed comprehensive evaluation framework offers a more sophisticated and nuanced approach to diagnosing ADHD in previously undiagnosed adults. By combining validated assessment instruments with thorough clinical investigation and collateral information, this model enhances diagnostic accuracy and treatment planning. Our findings suggest that this approach not only improves diagnostic precision but also provides valuable insights into the developmental trajectory of ADHD, leading to more personalized and effective treatment strategies.
Keywords: Adult ADHD, clinical evaluation, executive function, compensatory mechanisms, diagnostic precision

Discerning ADHD from comorbid Austim Spectrum Disorder, and using the Child and Adolescent approach when diagnosing and treating adults with ADHD

J. K. Suykerbuyk

Psychiatry - Rehabilitation, JKS-Miander, Antwerpen, Belgium
doi: 10.1192/j.eurpsy.2025.101

Abstract: Although Autism Spectrum Disorder (ASD) is frequently reported as a comorbidity in adults with Attention Deficit Hyperactivity Disorder (ADHD), diagnosing this additional condition in clinical practice remains challenging. Missing this diagnosis can significantly impact treatment and reduce the quality of life for these adults. In child and adolescent psychiatry, attention is also given to the source(s) that influence the symptoms and complaints of ASD and ADHD, both in diagnosis and treatment.
This lecture highlights the importance of identifying the source(s) of symptoms and complaints in adult patients, with or without ADHD, in an outpatient urban setting. Better mapping of these source(s) helps distinguish the symptoms of ASD from those of ADHD, refining both diagnosis and treatment. Unsurprisingly, ASD is often not even considered a potential comorbid condition in adults. In this lecture, we share practical experiences with adult outpatients and discuss the source(s) that frequently emerge, which aid in differentiating ASD symptoms from those of ADHD.

Cognitive impairment in psychoses and affective disorders: addressing future challenges

G. Sachs[1]* and A. Erfurth[1,2]

[1]Medical University of Vienna and [2]1st Department of Psychiatry and Psychotherapeutic Medicine, Klinik Hietzing, Vienna, Austria
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.102

Abstract: Cognitive dysfunction is well documented in patients with schizophrenia and bipolar disorder, including impairments in attention, memory, executive function and social cognition. These impairments are associated with poor social functioning and reduced activities of daily living.
Various therapeutic interventions have targeted cognitive impairment in both schizophrenic and bipolar patients. Several trials and meta-analyses are currently available. In addition to psychopharmacology, cognitive remediation programmes are available and have been shown to be applicable in clinical practice.
In conclusion, as we move towards more integrative and personalised treatment strategies for schizophrenic and bipolar patients, new assessments and therapies are available to target cognitive dysfunction. Not least because there are currently no cognitive enhancers on the market, it is hoped that new pharmacological adjunctive strategies can improve cognition in schizophrenia and bipolar disorder.

Functional dysconnectivity in Schizophrenia and Bipolar Disorder: associations with cognitive impairment

G. Cattarinussi[1,2]

[1]Department of Psychological Medicine, King's College London, London, United Kingdom and [2]Department of Neuroscience, University of Padova, Padova, Italy
doi: 10.1192/j.eurpsy.2025.103

Abstract: Background: Abnormal cerebellar functional connectivity (FC) has been independently implicated in the pathophysiology of schizophrenia (SCZ) and bipolar disorder (BD). However, the relationship between cerebellar dysconnectivity patterns in these two disorders and their association with cognitive functioning and clinical symptoms have not been fully clarified. In this study, we used the state-of-the-art functional atlas of the cerebellum to examine cerebellar FC changes in the SCZ–BD spectrum and their association with cognitive and clinical variables.
Methods: Resting-state functional magnetic resonance imaging (fMRI) data of 39 individuals with SCZ, 43 BD type I and 61 healthy controls were examined. The cerebellum was parcellated into ten functional systems and we calculated seed-based FC for each cerebellar system. Cognitive abilities were investigated with the Wechsler memory scale, the California Verbal Learning test, the Stroop test, the Attentional network task, the Continuous performance test, the Task Switch task and the Stop Signal task. Psychopathological evaluation was carried out using the Scale for the Assessment of Negative Symptoms and the Scale for the Assessment of Positive Symptoms. We used principal component analyses to reduce the dimensionality of the diagnosis-related FC and cognitive variables, respectively. Multiple regression analyses were conducted to assess the relationship between FC and cognitive and clinical data.
Results: We observed lower cerebellar FC with the frontal, temporal, occipital and thalamic areas in SCZ, and a more widespread decrease in cerebellar FC in BD, involving the frontal, cingulate, parietal, temporal, occipital and thalamic regions. SCZ presented increased within-cerebellum and cerebellar-frontal FC compared to BD. Higher cortico-cerebellar FC was positively associated with memory (p-FWE=0.036) and verbal learning (p-FWE=0.043). Exploratory analyses showed a negative correlation between cortico-cerebellar FC and positive symptoms (p-FWE=0.051).
Conclusions: These findings suggest a role for shared and distinct patterns of corticocerebellar dysconnectivity in the SCZ–BD spectrum that can result in cognitive impairment and psychotic symptoms. In addition, they highlight the potential role of cerebellar stimulation as a promising intervention for individuals with SCZ and BD-I that present cognitive impairment.

Multivariate Patterns of Cognitive and Socio-Cognitive Deficits in Schizophrenia, Bipolar Disorder, and related risk

A. Raio[1]* and L. A. Antonucci

Department of Translational Biomedicine and Neuroscience, University of Bari, Bari, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.104

Abstract: Alterations in cognition and social cognition in bipolar disorder and schizophrenia have been largely documented. However, to which extent these alterations overlap between the disorders and how they are relevant to early stages as well as to risk conditions remains unclear. To shed light on this topic, 59 patients with Bipolar Disorder (BD), 118 patients with schizophrenia (SCZ), two independent cohorts of Healthy Controls (HC1=95, HC2=195), as well as individuals at Clinical High Risk (CHR=35) and at First Episode of Psychosis (FEP=29) were characterized for a series of cognitive and socio-cognitive features, which were entered in a machine learning analysis as a cognitive, a socio-cognitive, and a combined cognitive and socio-cognitive (stacking) classifier. Such classifiers were probed to discriminate at the single subject level BD vs. HC1 and SCZ vs. HC2. Then, those with the greatest diagnostic power in categorizing BD vs. HC1 were challenged to predict discrimination between SCZ vs. HC2, and vice-versa. Thus, decision scores for such models were compared with those obtained when they were applied to FEP and CHR. Results indicated that stacking classifiers were the best in discriminating HC1 vs. BD (Balanced Accuracy - BAC = 80%) and HC2-SCZ (BAC = 84%). Furthermore, the HC1-BD staking classifier successfully discriminated HC2 from SCZ (BAC=77.4%), and vice-versa (BAC=83.1%). Decision scores for SCZ and BD overlapped with those obtained when stacking models were applied to FEP, identifying a "patient-like" pattern. Differently, when such combined signatures were applied to CHR individuals, they were classified neither as patients nor as HC. Findings suggest an overall overlap of cognitive and socio-cognitive anomalies classifying schizophrenia and bipolar disorder, which is also relevant to early stages of disease. In this general context, disease-specific core abnormalities characterize SCZ and BD. Personalized rehabilitative programs may be oriented to primarily manage disease-related cognitive and socio-cognitive "hub" alterations, but always within a broader assessment.

Genetics and other biomarkers of treatment resistance in depression

C. Fabbri

Department of Biomedical and NeuroMotor Sciences, University of Bologna, Bologna, Italy
doi: 10.1192/j.eurpsy.2025.105

Abstract: Major depressive disorder (MDD) is the most heterogeneous psychiatric disorder, as over 1400 combinations of symptoms can satisfy DSM diagnostic criteria, and understanding the underlying biological heterogeneity is fundamental in the perspective of precision psychiatry. Genetic variants are responsible for part of this heterogeneity and contribute to inter-individual differences in treatment effects. Therefore, pharmacogenetic studies can identify predictors of poor treatment response and treatment-resistant depression (TRD), aid the prescription and development of targeted treatments or the prescription of early intensive treatments in patients at risk of TRD. Previous genome-wide association studies (GWASs) had limited power to identify specific variants/genes involved in TRD, but polygenic overlap between poor antidepressant response/TRD and several other traits was demonstrated, e.g., schizophrenia, attention deficit hyperactivity disorder (ADHD), and cognitive traits. As suggested by the high clinical heterogeneity of MDD, considering specific symptom profiles can improve the power to identify genetic signals associated with TRD. Other promising strategies to identify the biological mechanisms involved in TRD include the study of large population cohorts, using proxies of TRD defined from electronic health records (EHRs), and the integration of biomarkers reflecting also environmental factors, such as proteomics. These strategies and ongoing studies will be discussed during this talk, with reference to Psych-STRATA, a project within the Horizon Europe research and innovation programme (101057454; https://psych-strata.eu).

Definition and neurobiological underpinnings of treatment resistance in bipolar disorder

L. Jonsson

Department of Psychiatry and Neurochemistry, Institute of Neuroscience and Physiology at the Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden
doi: 10.1192/j.eurpsy.2025.106

Abstract: The pharmacological treatment strategies for bipolar disorders include both acute and maintenance treatments. However, a substantial number of patients do not respond sufficiently to pharmacotherapy. Thus far, there has been no standardized definition for treatment resistance in bipolar disorder. Studies have been using different definitions, possibly due to the clinical complexity including the episodic nature of bipolar disorder and various subtypes. The talk will discuss the definitions, neurobiological, and genetic aspects as well as ongoing initiatives to identify markers for treatment resistance in bipolar disorder.

SP025

Neurobiological characteristics of treatment resistance and predictors of treatment tolerability for schizophrenia

E. Van Assche

Department of Psychiatry, University of Münster, Münster, Germany
doi: 10.1192/j.eurpsy.2025.107

Abstract: Schizophrenia is a chronic disorder with a massive impact on quality of life. The prevalence of treatment resistance has been estimated around 30%. Treatment resistance is typically defined as non-response to 2 antipsychotics *of adequate dose and duration*. However, clinical reality often shows that the definition at an individual level is more complex and a personalised approach is needed.
We present a literature review discussing clinical, neurobiological and pharmacogenetic aspects relevant to treatment resistance.
Our overview highlights the need for indiviudalised assessement of patient needs. We discuss pharmacogenetic aspects related to treatment respons and tolerability, including Clozapine. We focus on indicators for stratification and treatment optimization in the context of personalised medicine. In addition, we present evidence for other augmenting treatment modalities in the context of treatment resistance for schizophrenia, such as neuromodulation (e.g., rTMS for acoustic hallucinations).
This talk focuses on the challenges of treatment resistance in schizophrenia and discuesses new insights in the existing treatments and pharmacogenetics, as well as opportunities for treatment augmentation that arise from emerging technologies.

Clinical, RCT and real word evidence for early intensive treatment and complex multimodal treatment of treatment resistant mental disorders

B. Baune* and The PsychSTRATA Study Group and the PROMPT Study Group

Department of Psychiatry, University of Münster, Münster, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.108

Abstract: Schizophrenia (SCZ), bipolar (BD) and major depression disorder (MDD) are severe psychiatric disorders that are challenging to treat, often leading to treatment resistance (TR). It is crucial to develop effective methods to identify and treat patients at risk of TR at an early stage in a personalized manner, considering their biological basis, their clinical and psychosocial characteristics. Effective translation of theoretical knowledge into clinical practice is essential for achieving this goal. We describe the methodology of the PROMPT project that aims at the development of a precision medicine algorithm that would help early detection of non-responder patients, who might be more prone to later develop TRD. In addition, we demonstrate other ongoing comprehensive protocols in Precision Psychiatry, such as the Horizon Europe funded PsychSTRATA consortium. To address these objectives, the PROMPT project which is organized in 2 phases will involve 300 patients with MDD already recruited in phase 1, comprising 150 TRD and 150 responders. In phase 2, a new naturalistic cohort of 300 MDD patients will be recruited to assess, under real-world conditions, the capability of the algorithm to correctly predict the treatment outcomes. Moreover, in this phase a shared decision making (SDM) process in the context of pharmacogenetic testing is explored and various needs and perspectives of different stakeholders toward the use of predictive tools for MDD treatment to foster active participation and patients' empowerment are evaluated. In addition to this effort, the Psych-STRATA consortium addresses a major research gap in Precision Psychiatry through a seven-step approach. First, transdiagnostic biosignatures of SCZ, BD and MDD are identified by GWAS and multi-modal omics signatures associated with treatment outcome and TR (steps 1 and 2). In a next step (step 3), a randomized controlled intervention study is conducted to test the efficacy and safety of an early intensified pharmacological treatment. Following this RCT, a combined clinical and omics-based algorithm will be developed to estimate the risk for TR. This algorithm-based tool will be designed for early detection and management of TR (step 4). This algorithm will then be implemented into a framework of shared treatment decision-making with a novel mental health board (step 5). The final focus of the project is based on patient empowerment, dissemination and education (step 6) as well as the development of a software for fast, effective and individualized treatment decisions (step 7). Both the PROMPT study and the PsychSTRATA project have the potential to change the current trial and error treatment approach towards an evidence-based individualized treatment setting that takes TR risk into account at an early stage.

A case report about autism spectrum disorder and comorbidities: diagnostic and treatment difficulties in transition from adolescence to adulthood

B. F. Farkas[1]* and J. Á. Balázs[2,3]

[1]Department of Psychiatry and Psychotherapy, Semmelweis University; [2]Institute of Psychology, Eötvös Loránd University, Budapest, Hungary and [3]Oslo New University College, Oslo, Norway
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.109

Abstract: We report the case of an 18-year-old male patient diagnosed with autism spectrum disorder at age of 12. Between the age of 12 and 18 he developed anxiety and substance use disorders.
He was acutely admitted to the Department of Psychiatry and Psychotherapy at Semmelweis University due to a severe manic episode with psychotic symptoms at the age of 18. He provided a multidisciplinary treatment, including medication, support group, individual addiction consultation and rehabilitation. He became stable, currently abstinent for six months and planning to graduate.
Our case report has practical implications for physicians by raising their awareness of comorbid mental disorders in the autism spectrum and also the difficulties in the transition between adolescence to adulthood.
Keywords: autism spectrum, comorbidity, transient psychiatry

The experience of transition to adult services of young people with neurodevelopmental disorders and mental health problems

J. Santambrogio[1]*, M. Marchetti[2,3], Alessandra Beretta, Erika Morandi, Francesca Formaggio, Ilaria Ruberto, Milena Danese, Giuseppina Redaelli, Massimo Clerici, Sergio Terrevazzi, Antonio Amatulli and Armando D'Agostino

[1]Department of Mental Health and Addiction, Disability Unit, ASST Brianza, Limbiate; [2]Department of Mental Health and Addiction, ASST Valle Olona, Busto Arsizio and [3]Department of Health Sciences, University of Milan, Milano, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.110

Abstract: Background: Transitional care refers to the coordination and continuity of care between different healthcare locations or levels of care within the same facility, regardless of the patient's age. Transition planning and management is therefore a key element in the organization and delivery of health services. Unfortunately, for many young people with mental health problems, transition is poorly planned, lacks coordination, and results in discontinuity of care. This is particularly true for intellectual disability, Autism Spectrum Disorder, and ADHD: as neurodevelopmental conditions, care typically begins at a young age with attendance at Child and Adolescent Mental Health Services (CAMHS), and the transition to Community Mental Health Services (CMHS) encounters numerous challenges.
Methods: A narrative review of the literature was conducted on the topic of transition from inception to January 26th, 2025. The following search string was used through PubMed, Web of Science, Scopus, and PsychInfo: ("Transitional Care" OR "Transition to Adult Care") AND ("Neurodevelopmental Disorders" OR "Intellectual Disability" OR "Autistic Disorder" OR "Autism Spectrum Disorder") AND ("Child and Adolescent Mental Health Services" OR "CAMHS" OR "Community Mental Health Centers").
Results: A total of 202 references were identified and screened considering titles and abstracts. After excluding papers not relevant to the topic and those that were unretrievable, 31 papers were included in the review. A significant majority of the included papers were qualitative studies based on focus groups and interviews conducted with family members and caregivers.
Discussion and conclusions: Findings reveal a lack of clarity and consistency regarding service availability for the conditions studied, possibly due to different eligibility criteria between child and adult mental health services, with variable service provision for young people with neurodevelopmental conditions (specifically, ASD, ADHD and ID). While high workloads and staff shortages were perceived to influence service thresholds and eligibility criteria, the lack of perceived severity by the CMHS often led to loss of follow-up.

Transition of psychiatric care from childhood to adulthood: An opportunity for adult psychiatry

J. P. Coelho Silva Albuquerque* and EPA Section on Mental Health in Intellectual Disability

Centro de Recuperação de Menores, IIHSCJ, Assumar, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.111

Abstract: According to the American Academy of Child and Adolescent Psychiatry (AACAP), 50% of all lifetime cases of mental illness begin by age 14, and 75% by age 24 (1). Development is a lifelong process, but adult development is generally more gradual and less critical than that of children and adolescents. That is why the role of development in child psychiatry is particularly important, contrary to the adult psychiatry, more focused on the categorical definition of the observed clinical situation.
Autism Spectrum Disorders (ASD) in particular, characterized by heterogeneity, may evolve to adulthood with an atypical presentation. Approximately a quarter of autistic adults reported being misdiagnosed with at least one psychiatric condition before receiving an autism diagnosis. Personality disorders, mood disorders, and anxiety disorders were most frequently perceived as misdiagnoses, according to Fusar-Poli et al (2).
The contact between adult psychiatry and child and adolescent psychiatry, may be organized in transition care settings (outpatient care, clinical discussions, …). These practices may have a major impact in adult psychiatry practice, emphasizing the importance of a developmental approach, at any given time and with each patient, going beyond the classical inquiry about clinical and personal backgrounds. It also helps adult's psychiatrists to keep in mind diagnostic hypotheses of neurodevelopmental disorders, which are usually more focused on child and adolescent psychiatry.
A clinical case will be presented to illustrate our thesis.

Challenges faced by individuals with autism and intellectual disability as they prepare for adulthood

M. A. Ciołek

Medical University of Silesia, Katowice, Poland
doi: 10.1192/j.eurpsy.2025.112

Abstract: Individuals with autism and intellectual disability encounter numerous challenges as they transition into adulthood. By analyzing case studies of students in both specialized and mainstream educational settings, I aim to highlight their perspectives and experiences.
These individuals grapple with a myriad of hurdles, from difficulties in communication and social interaction to challenges in academic and vocational pursuits. Through case studies, we witness the personal and societal barriers they encounter, highlighting the need for tailored interventions and support systems.
Early intervention and specialized education play crucial roles in empowering these individuals to thrive. By providing nurturing

environments and equipping them with essential skills, we can foster independence and enhance their overall well-being. Additionally, community resources offer ongoing support beyond the school setting, further facilitating their transition into adulthood. Central to our discussion is the importance of fostering an inclusive society that embraces neurodiversity. When individuals with autism and intellectual disability are valued for their unique perspectives and talents, they can contribute meaningfully to society. Through acceptance and understanding, we can pave the way for a more equitable future for all.

Digital phenotyping of stress responsive suicidal ideation in healthy individuals: an opportunity for prevention

M. A. Oquendo MD, PhD

Psychiatry, University of Pennsylvania, Philadelphia, United States
doi: 10.1192/j.eurpsy.2025.113

Abstract: Background: Decedents without known mental disorders constitute 5%-40% of suicides and epidemiologic studies show that 20% of those with a history of suicidal behavior (SB) may be free of psychiatric disorders. This implies that suicide ideation (SI) may occur in the psychiatrically healthy volunteers (HVs), providing an opportunity for preventing suicide and SB. Yet, studies of HVs have not focused on the occurrence of SI, nor has SI in HVs been characterized, especially in relation to the occurrence of stress. If SI is not rare in HVs, current approaches to managing suicide risk in medical settings may be too limited to identify psychiatrically healthy individuals at risk for suicide.
Aims & Objectives: We recruited HVs and major depressive disorder (MDD) patients to test two hypotheses: (1) some HVs, screened to exclude those meeting lifetime criteria for Axis I or II disorders and with no personal or family history of SB, would endorse SI on Ecological Momentary Assessment (EMA); and (2) HVs' SI scores would be lower than those of MDD patients. In addition, we investigated whether HV and MDD groups had different responses to stressors in terms of SI.
Method: HVs and MDD patients were recruited through advertisements: some patients were recruited in the emergency department. Participants provided 7 days of ecological momentary assessment (EMA) data about SI and stressors. EMA data was collected in six 2-hour epochs during a 12-hour period selected to match participant wake hours. Longitudinal mixed effects logistic regression models compared HV and patient SI scores and frequency of stressors. Mixed effects linear regression models compared HVs' and patients' SI score change from the previous epoch's SI score when each stressor occurred.
Results: HVs (n=42) reported less frequent ($p<0.001$) and less intense SI ($p<0.003$) than patients (n=80). HVs did endorse SI and/or SI-related items in 44% of EMA epochs, endorsing actual SI items, as opposed to SI related items (lack of wish to live) in 25% of epochs with non-zero SI scores. For 7 of 8 stressors, patients reported stressors more often than HVs (all $p<0.001$) and responded to them with greater SI ($0.0001<p<0.0472$). HVs reported statistically significant SI increases only in response to neglect ($p<0.0147$), indicating HVs were relatively resilient to other stressors.
Discussion & Conclusion: The occurrence of SI and SB among psychiatrically healthy individuals has been relatively neglected. However, SI does occur in this population. Although HVs demonstrated more modest SI increases than patients in response to stressors, the reports of SI in 44% of epochs by HVs suggest that focusing solely on individuals with mental disorders when screening for suicide risk may be too narrow an approach.

Phenotyping suicidal behaviour: what could we learn from digital and experimental studies

P. Courtet

University, Montpellier, France
doi: 10.1192/j.eurpsy.2025.114

Abstract: Digital studies based on the continuous monitoring of patients in their natural environment help to refine the suicidal phenotypes. Studies using ecological momentary assessment revealed the existence of different patterns of suicidal ideation (SI) based on both their severity and variability. Specifically, variable SI may be a frequent pattern of suicidal ideation that appears to be related to some clinical features (social withdrawal, impulsive aggression, suicide attempts), rooted in childhood trauma and serotonergic dysfunction and associated with the reactivity to stressful life events. Some individuals, in response to stress could experience both psychological pain and decision-making impairment in social contexts, leading to suicide risk. Then, the description of the suicidal pattern may help to define clinically and biologically homogeneous groups of at-risk patients.
In this sense, experimental studies where patients are submitted to a social stress task reported that patients who were more sensitive to a social stress, as measured with a higher salivary cortisol response, were less depressed, more impulsive, and made suicide attempts with a higher intent. Investigating the regulation of the immune inflammatory response to the social stress task, we recently reported that suicide attempters and ideators showed less dynamic inflammatory stress responses in comparison to psychiatric controls, and that platelet activation responses to stress were blunted in individuals with suicidal ideation. Last, we will present new data of cardiovascular and emotional responses to the virtual Trier Social Stress Test in women with a history of depression and with or without a history of suicide attempt. Combining digital and experimental studies could help to refine the suicidal phenotypes and reduce the heterogeneity of suicidal behaviors that are led by different processes, in order to develop specific therapeutic approaches for a better suicide prevention.

SP034

Cognitive Behavioural Therapy/Motivational Interviewing in Emergency Settings in Child and Adolescent Psychiatry

T. Gargot

Child and Adolescents psychiatry, University Hospital Tours, Tours, France
doi: 10.1192/j.eurpsy.2025.116

Abstract: Worldwide, suicidal ideation in youth varies between 14% and 23 %. Between 5% and 16% have made a suicidal attempt. The prevalence has increased recently. However, we measure a decrease in suicide deaths (Van Meter et al., 2021). Suicide is the second cause of death after accidents. Most psychiatric disorders appear during or before adolescence (Solmi et al., 2022), which makes it a critical period to begin treatment. Development induces peculiarities like more dependence on the environment, insight difficulties, and impulsivity.

Risk factors should be assessed like previous suicidal attempt history, active suicidal ideation, trauma, alcohol misuse, and drug misuse (Pernau et al., 2024).

The management of these situations stresses several challenges. Several interventions were designed but did not show specificities on subsequent suicide prevention. However, they decreased immediate psychiatric hospitalisations, increased mental health service use, and showed mild improvement in subsequent depressive symptoms (Pitt et al., 2024).

Studies in non-specific factors and therapeutic alliance operationalized in motivational interviewing open perspectives like the importance of reflective listening, open questions, semi-directivity and shared objectives (Miller & Moyers, 2021).

Understanding of depression enlightens specific simple approaches like behavioral activation (Richard et al., 2016; Kanter et al., 2010) and problem-solving therapy (Bell & D'Zurilla, 2009).

Specific tools like joint crisis plans (Jong et al., 2016) are useful and ethical on paper or in apps (Stanley et al., 2018)

Organization of care is of paramount importance like phone and letters contact like the program Vigilans (Plancke et al., 2020).

Bibliotherapy and internet CBT tools (Linardon et al, 2024 ; Hedman-Lagerlöf, et al., 2023 ; Lewis et al., 2012) could be useful to improve mental health care accessibility with a small cost.

SP035

Psychotherapeutic Interventions in Humanitarian Settings

S. Tanyeri Kayahan

Psychiatry, Republic of Türkiye Ministry of Health Yalvaç State Hospital, Isparta, Türkiye
doi: 10.1192/j.eurpsy.2025.117

Abstract: Humanitarian crises result from various events threatening many individuals' health, safety, and well-being. The frequency of public health crises has increased within the last decades, posing significant risks to health, particularly for people in low- and middle-income countries. Social determinants such as discrimination, poverty, and violence are risk factors for mental health conditions. People living through humanitarian crises might experience mental distress, with challenging circumstances that lead to vulnerability to developing mental disorders, including depression, anxiety disorders, and post-traumatic stress disorder.

Psychotherapy in humanitarian settings mainly refers to providing psychological support and treatment to individuals affected by wars and armed conflicts, famine, and natural disasters such as earthquakes, hurricanes, or floods. Humanitarian settings pose unique challenges to the delivery of mental health services due to disrupted infrastructure, cultural differences, and the complex needs of affected individuals. Therefore, psychotherapeutic interventions in humanitarian settings should recognize the psychological and social aspects of mental well-being for prevention and treatment. The psychological components of such interventions are related to the mental and emotional state of the person. Social components include efforts to strengthen social support and interpersonal skills, promoting positive aspects of mental health.

In humanitarian settings, mental health care is often integrated with other services, such as education and social services. This holistic approach ensures that mental health is addressed with basic needs like food, shelter, and safety. Another critical aspect is ensuring the safety and mental well-being of therapists at risk in conflict zones. Although limited evidence shows their effects on better mental health outcomes, several therapeutic modalities are frequently used in humanitarian settings, adapted to unique circumstances. Those include cognitive-behavioral therapy, group therapy, trauma-focused psychotherapy, mindfulness and stress reduction, narrative therapy, and interpersonal psychotherapy.

In conclusion, psychotherapy in humanitarian settings plays a crucial role in addressing the mental health needs of individuals affected by crises. It requires flexibility, cultural sensitivity, and a multidisciplinary approach to overcome the challenges posed by these environments. Digital platforms and web-based services might offer accessible and resourceful therapy options. However, further research is needed to evaluate the effectiveness of psychosocial interventions in such settings. Efforts to expand real-world solutions in mental health services, build local capacities, and integrate psychosocial support into broader humanitarian assistance in low-resourced settings are essential to fostering recovery and resilience in affected populations.

Transforming mental health implementation research

E. Mcginty

Health Policy & Economics, Weill Cornell Medicine, New York, United States
doi: 10.1192/j.eurpsy.2025.118

Abstract: Slow and inadequate implementation causes greater inequity and reduced quality in emergency psychiatric services. This symposium is based on five recommendations to improve health intervention research and implementation, presented by Professor Emma Mcginty (PhD), the leader of the Lancet Psychiatry Commission to transform implementation in mental health. This presentation will introduce each of these recommendations: I)

integrate research into clinical practice to ease implementation II) embed equity in mental health intervention research III) use complexity science and bottom-up approaches to improve relevance of science and implementation IV) base implementation less additional methods beyond traditional RCT-based research V) use a transdisciplinary approach in development and implementation of research on new interventions.

A systematic review of theories, models and frameworks used to guide or evaluate the implementation of coercion reduction programs

T. Lantta[1,2,3]* and COST Action FOSTREN (Fostering and Strengthening Approaches to Reducing Coercion in European Mental Health Services)

[1]University of Turku, Turku, Finland; [2]Swinburne University of Technology, Melbourne, Australia and [3]University of Modena and Reggio Emilia, Reggio Emilia, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.119

Abstract: Coercive practices in mental health care can infringe upon human rights, necessitating urgent global action to eliminate them. However, inconsistencies in clinical practice, fragmented research on effectiveness, and limited understanding of barriers and facilitators hinder the real-world transformation of services. As part of the COST Action FOSTREN (Fostering and Strengthening Approaches to Reducing Coercion in European Mental Health Services), Working Group 4 Implementation Science conducted a systematic review to examine the models, theories and frameworks employed by studies in implementing programs aimed at reducing coercion in mental health settings and the reported implementation outcomes. A comprehensive search was conducted across multiple databases, resulting in the inclusion of eight studies (nine papers). The identified coercion reduction programs utilized holistic approaches, risk assessment methods, staff training, and sensory modulation interventions. All of them were conducted in inpatient settings. Eight different implementation tools were identified, but none of the studies reported all sought implementation outcomes. The most frequently reported outcomes were acceptability and adaptation, while no studies provided data on implementation costs. Overall, the quality of the studies assessed was relatively low. The review highlights the underutilization of systematic implementation models, theories and frameworks when embedding coercion reduction interventions in routine mental health care, especially in emergency psychiatry settings. Further research, incorporating the perspectives of service users and carers, is needed to address this gap and determine the costs and resources required for implementing complex interventions with implementation models, theories and frameworks guidance.

Open-door policy in urban acute wards: results and implementation experiences from a five-year staff co-created in-clinic RCT

N. Kunøe[1,2]

[1]The Lovisenberg Diaconal Hospital and [2]The University of Oslo, Oslo, Norway
doi: 10.1192/j.eurpsy.2025.120

Abstract: Open-door policy is a WHO-recommended framework to maximise safety, prevent coercion, and enhance recovery-based practices during admission to mental health wards. This talk will describe the open-door policy intervention, present results from our 1-year RCT and preliminary 5-year results from the Lovisenberg Open Acute Door Study (LOADS). LOADS is a 5-year in-clinic dual RCT study of open-door policy co-created with user representative and staff in our inner-city acute mental health wards in Oslo, Norway. By combining random allocation, effectiveness outcomes and implementation research, LOADS aims to address the need for faster development of clinically relevant knowledge in mental health.

SP039

Excessive Alcohol Consumption, Alcohol Use Disorder and Women

R. Agabio[1]* and F. Salis

Department of Biomedical Sciences, University of Cagliari, Monserrato (CA), Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.121

Abstract: Alcohol is a major risk factor for mortality and morbidity worldwide (Agabio et al., 2017). Women are affected by specific alcohol-related consequences, including a dose-dependent increased risk of breast cancer from relatively low levels of alcohol consumption, of which many women remain unaware (Agabio et al., 2022), and risk of foetal alcohol syndrome, in their offspring, if alcohol is consumed during pregnancy (Minozzi et al., 2024). Alcohol use disorder (AUD) is a severe and frequent mental disorder with devasting consequences (Agabio et al., 2017). In US, approximately one out of 4 women suffer for this disorder during their lifetime (MacKillop et al. 2022). Although effective treatments are available (Agabio et al., 2024), AUD is undertreated, with stigma being one of the main reasons for not seeking medical treatment (MacKillop et al. 2022) Women usually experience more severe barriers to AUD treatment than men, with pregnant women experiencing more severe barriers than non-pregnant women (Agabio et al., 2017). Another reason of the scarce use of medical treatment is constituted by the widespread belief that available medications are not effective, or rather, are not

effective for all people with AUD. Although sex and gender differences have been described in the response to medications, AUD medications have been studied almost exclusively in men (Agabio et al., 2016). In addition, the number of women with AUD is increasing and services for treatment of AUD should (a) consider women's specific needs, and (b) realize effective policies to reduce latency prior to accessing medical treatment for both men and women with AUD (Agabio et al., 2021). Nevertheless, recent studies show that only a small number of services have adopted a gender medicine approach in AUD treatment (Vignoli et al., 2024).

Gender perspective of dual diagnosis

J. Tirado Muñoz

Department of Psychology, Universidad Europea de Madrid, Madrid, Spain
doi: 10.1192/j.eurpsy.2025.122

Abstract: Dual diagnosis, the co-occurrence of substance use disorders (SUD) and mental health conditions, presents unique challenges influenced by gender-related factors. This narrative review explores the role of gender in the epidemiology, treatment access, environmental factors such as intimate partner violence, clinical features, and outcomes of dual diagnosis, highlighting structural and social determinants that exacerbate disparities. Women and gender minorities with dual diagnosis face heightened stigma, higher rates of trauma, and significant barriers to healthcare, often resulting in delayed treatment and poorer prognoses. Additionally, traditional gender roles and caregiving responsibilities influence coping mechanisms and treatment adherence. Despite increasing awareness, research on gender-responsive interventions remains limited. This review underscores the need for gender-sensitive approaches in dual diagnosis treatment, advocating for integrated, trauma-informed care that addresses the specific needs of diverse gender identities.

Precision Medicine in the treatment of alcohol dependence – the role of gender

H. Walter

MedUniWien i.R., Vienna, Austria
doi: 10.1192/j.eurpsy.2025.123

Abstract: Clinically derived approaches take the different psychosocial and biological conditions into regard and thus render more homogeneous groups, than the current diagnostic criteria, like ICD-11 or DSM 5. Precision medicine, moreover, shows that the amount of drinking, the reason for drinking and thereby also gender seems to be relevant for testing different anticraving drugs. Precision medicine indicates the necessity for more homogeneous subgroups, in order to find differences in the effects of anticraving substances. Many typologies in AUD render more homogeneous subgroups (Lesch et al, 2020). They could increasingly be used for testing anticraving drugs. After presenting these basics in anticraving research, the results of two trials will be presented. First, some genetic results could only be defined in Lesch type 3 female patients (Procopio et al, 2013). Second, in a treatment trial of ondansetron the genetic conditions lead to better sobriety rates only in the not very high drinking group (less than 10 drinks per day) but not in the very high drinking group (Addolorato et al, 2024). Summarizing these research results we see that for anticraving trials we need even more carefully defined subgroups of AUD patients. Menstrual Cycle and Progesterone as Future Treatment Targets of Alcohol Use Disorder

B. Lenz* and ReCoDe Consortium

Addictive Behavior and Addiction Medicine, Central Institute of Mental Health, Mannheim, Germany

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.124

Abstract: Alcohol use disorder (AUD) has a significant impact on the individuals affected, their relatives, and the society at large. Given the limited efficacy of currently available treatments, there is a pressing need for a more comprehensive mechanistic understanding. In particular, consideration must be given to the dynamical and real-world aspects. The objective of this study was to investigate the association of dynamic variations across menstrual cycle phases (indicative of progesterone-to-estradiol ratios) in women with AUD and progesterone-to-estradiol ratios in men with AUD with real-world problem drinking. To this end, longitudinal data from the German TRR265 cohort (comprising smartphone entries on alcohol consumption, craving, and loss of control, self-reports on menstrual cycle phases, and blood progesterone-to-estradiol ratios) were subjected to analysis. In women with AUD, the lowest levels of problem drinking, craving, and loss of control were observed during the late luteal phase, when the progesterone-to-estradiol ratios reached their peak. Similarly, in men with AUD, higher progesterone-to-estradiol ratios were associated with lower problem drinking, craving, and loss of control. Some of these effects were moderated by the severity of the AUD. The results highlight the progesterone-to-estradiol ratio as a promising future treatment target and point to the necessity of cycle phase-tailored treatments for women with AUD.

Mental Health Liaison Program with Schools in Madrid

C. Arango

Hospital General Universitario Gregorio Marañon, UCM, CIBERSAM, Madrid, Spain
doi: 10.1192/j.eurpsy.2025.125

Abstract: Mental health issues among children and adolescents have risen, particularly following the COVID-19 pandemic. Despite increased awareness, less than half receive necessary care, leading to long-term consequences. The World Health Organization advocates for integrated, preventive community interventions to address this gap. This paper presents the **Mental Health Clinical Liaison Programme for Schools** in the Community of Madrid, Spain, which provides school-based activities led by multidisciplinary mental health teams. The programme focuses on early detection, intervention, and prevention strategies for children and adolescents. We describe its implementation, review supporting evidence, provide preliminary data, and discuss its scope and challenges. Between 2023 and 2025, the programme has reached over 100 primary and secondary schools, identifying more than 1,700 cases, evaluating over 500 students, and referring 232 to specialized services. It has also supported interventions for more than 400 students already in mental healthcare and facilitated 45 reintegrations following psychiatric hospitalization. Additionally, anti-stigma workshops have engaged approximately 2,500 students. Ongoing research aims to assess the programme's effectiveness and cost-effectiveness to ensure continuous improvement in mental health services for young people.

Mental Health Interventions in Special Education Schools

L. M. Sevilla Cermeño

Department of Child and Adolescent Psychiatry, Hospital General Universitario Gregorio Marañón, Madrid, Spain
doi: 10.1192/j.eurpsy.2025.126

Abstract: Children in special education schools are particularly susceptible to developing mental health issues. Specifically, it is estimated that 40% of individuals with intellectual disabilities have a comorbid mental disorder diagnosis (1). However, access to mental health services for patients with intellectual disabilities remains far below expectations. Numerous barriers impede this access, including a lack of coordination between professionals and service providers responsible for their care (2).

Therefore, interventions within special education schools, promoting early detection and intervention for psychopathology and facilitating coordination between educational and healthcare services, are critically important.

We present an innovative mental health care resource designed for special education schools in the Community of Madrid, Spain. This initiative combines multi-disciplinary expertise with flexible, hybrid care delivery to ensure accessibility for students across 14 public schools. The team consists of a psychiatrist, a clinical psychologist, and a mental health nurse who provide both in-person and remote assistance, addressing the psychopathology exhibited by their students.

Preliminary results suggest that this intervention has the potential to improve early detection rates of mental health issues and foster better coordination between education and healthcare systems. This model could serve as a blueprint for similar programs worldwide, addressing significant gaps in mental health care for children with intellectual disabilities.

Care Policy and Evaluation Centre, Department of Health Policy, London School of Economics and Political Science, London, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.127

Abstract: Children and young people spend much time in school and therefore the school setting provides an important setting in which to intervene to promote, protect and enhance mental health. This presentation will provide an overview of the importance of making an economic case for action within schools. A scoping review has been undertaken to map the types of interventions that have been subject to cost-effectiveness evaluation. Aspects of the strengths and weakness of the existing evidence are presented. Implementation and sustainability challenges are also discussed, given the need for collaboration between the health and education sectors.

How can we improve the access of forcibly displaced people to mental health care in Europe?

M. Schouler-Ocak

Psychiatry and Psychotherapy, Charité - Universitätsmedizin Berlin, Berlin, Germany
doi: 10.1192/j.eurpsy.2025.129

Abstract: A growing body of literature report, that vulnerable groups eg refugee, asylum seeker and forcibly displaced groups across Europe face social and psychological challenges linked to their minority status, often involving discrimination and racism. Moreover, they have to overcome many other barriers to accessing healthcare and preventive interventions. There is increasing evidence that a large proportion of refugees or forcibly displaced persons suffer from the consequences of traumatic events and exhibit psychological problems or develop mental disorders, including post-traumatic stress disorder, depressive and anxiety disorders, and relapses in psychotic episodes. European countries are aware that psychosocial and health services face major challenges and need to develop or expand strategies to overcome them. The direct and indirect consequences of humanitarian catastrophes cannot be estimated at present. In this presentation, strategies to improve the access of forcibly displaced people to mental health care services will be presented and discussed.

Long-Term Outcomes in First-Episode Psychosis: Insights from a 20-Year Cohort Study to Inform Recovery-Oriented Care Models

M. N. Clarke

Psychiatry, St John of God Community Mental Health Services, Dublin, Ireland
doi: 10.1192/j.eurpsy.2025.130

Abstract: Background: Cohort studies in first-episode psychosis (FEP) provide crucial insights into the diverse trajectories of clinical and functional recovery. These studies are invaluable for evaluating the effectiveness of new intervention models and informing resource allocation and policy development.
Objectives: To synthesize quantitative and qualitative findings on mortality and clinical outcomes and to explore their interrelations in a multi-modal investigation of long-term outcomes in FEP. Specific objectives include appraising how this study's findings have influenced the development of new models of care.
Methods: Data were drawn from the iHOPE-20 study, comprising cohort analyses and qualitative interviews with 171 FEP participants diagnosed between 1995–1999 in Dublin, Ireland. Participants with lived experience contributed to the design of the 20-year follow up assessments. Mortality rates were calculated; symptoms, functionality and quality of life trajectories were analyzed using mixed models; and personal recovery themes were derived through thematic analysis. Ongoing analyses are addressing predictors of the number, timing and sequencing of relapses/readmissions among baseline variables as foci for service development.
Results: The study revealed substantial variation in long-term outcomes among individuals with FEP. Shorter DUP was consistently associated with better outcomes across all of the follow-up points. Mortality rates highlighted the importance of interventions to address physical health morbidity. Diagnostic instability over time underscored the dynamic nature of psychosis management. Employment status at follow-up highlighted the importance of strategies to support a return to education or employment after a first presentation.
Conclusions: Findings emphasize the enduring impact of DUP and the need for tailored interventions. Data from this cohort highlight the value of longitudinal insights as a benchmark for comparing the effectiveness of new intervention models. In such studies, addressing ethical and data protection challenges, incorporating the expertise of those with lived experience and harmonising outcome measures remain vital to advance recovery-oriented care models.

Early development of physical co-morbidity and premature death in long-term first-episode psychosis cohorts

J. Vázquez-Bourgon* and PAFIP & ITPCan

Marques de Valdecilla University Hospital, Santander, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.131

Abstract: People with psychosis present a significantly higher premature death, leading to a reduction of life expectancy of up to 15-20 years.
To a high extent, this premature mortality is due to a higher incidence of common physical conditions, appearing earlier than in the general population. Traditionally, the focus has been put on the cardiovascular diseases. However, more recently, there ir mounting evidence of the contribution of other conditions to this premature mortality, such as repiratory (e.g.: chronic obstructive pulmonary disease) and liver (MAFLD) conditions.
We are presenting results from PAFIP and ITPCan early intervention programs (Cantabria, Spain), regarding the early impact of psychosis on physical health, observing early alterations at the organic level (e.g.: liver, lung), which precede the development of chronic organic pathology causing premature mortality in the general population.

Long-term prognosis of schizophrenia in a Danish context

H. G. Hansen[1]* and M. Starzer[2]

[1]Department of Clinical Medicine, University of Copenhagen, Denmark, Copebhagen Research Center for Mental Health and [2]Department of Clinical Medicin, University of Copenhagen, Denmark, Copenhagen Research Center for Mental Health, Hellerup, Denmark
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.132

Abstract: The Danish OPUS trial was originally a randomized controlled trial testing Early Intervention Services among individuals diagnosed with schizophrenia spectrum disorders between the years 1998-2002. Today, the OPUS trial includes a unique cohort of individuals (n=578) longitudinally followed and clinically assessed for more than two decades after a first diagnosis within the schizophrenia spectrum. Using longitudinal Danish register data and clinical data from the Danish OPUS cohort, we explored the effects of early intervention services including symptom remission, use of antipsychotics, hospitalization, global functioning and other aspects of life including social relations, parenthood, and mortality.
Results: Investigating modern-era treatment facilities in 20 years of follow-up of the OPUS trial, we found no evidence for long-term disease-modifying effects from two years of Early Intervention Services compared to Treatment as Usual. While a majority of participants experienced a reduction and stabilization of psychotic symptoms over time it seems half of all the participants experienced no significant improvements in negative symptoms. Still, 17% were in clinical recovery, and 40% were in symptom remission. Combining clinical data from the Danish OPUS cohort with the Danish registers, we found that 29% (n=120) of individuals were in current treatment with antipsychotic medication after 20 years of follow-up. A total of 36% (n=51) of the clinical sample were in remission of psychotic symptoms and off antipsychotics with better clinical outcomes compared to individuals in non-remission off/on medication. Additionally, a substantial proportion of 38% (219 out of 578) of individuals in the OPUS cohort had become parents over two decades, and on average, they had better functional and clinical outcomes than their counterparts without children. A mortality rate of 14.2 was found. Suicide was the single most common cause of death, but death due to natural causes and death due to unnatural causes made of roughly half of all deaths each.
Conclusions: While many patients may achieve remission of psychotic symptoms, our findings suggest negative symptoms are of a much more chronic nature. Investigating the use of antipsychotics over 20 years a substantial proportion were in remission and off medication. Since an observational study design cannot differentiate between cause and effect, these individuals still set a benchmark for good outcomes in schizophrenia. Also, 38% of individuals had become parents over two decades, and cross-sectionally, they had better illness prognosis and lifetime course than their counterparts without children. Finally, one in seven of the participants in the OPUS trial had died during follow-up. Suicide is a vital problem even many years after diagnosis and suicide-preventive measures are needed in the later course of illness.

Twenty-year follow up of the TIPS study

W. T. V. Hegelstad[1,2] and M. Weibell[1,3]*

[1]TIPS Centre for Clinical Research in Psychosis, Stavanger University Hospital; [2]Faculty of Social Sciences, University of Stavanger, Stavanger and [3]Medical Faculty, University of Bergen, Bergen, Norway
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.133

Abstract: Background: Comparing long-term outcomes in psychosis can be challenging due to widely differing definitions, measures, and populations. The remission working group led by Andreasen et al. suggested remission criteria based on positive symptoms and duration. However, there is no internationally agreed definition of functional recovery. The TIPS study is one of very few with very long-term follow-up, and this presents a unique opportunity both to investigate outcomes as well as use findings to develop valid definitions for the future.
Objective: In this longitudinal study, we explore remission patterns and functional status with regards to social contacts, living situation and employment status over 20 years.

Methods: A representative sample originally consisting of 201 first episode psychosis patients from two Norwegian well defined catchment areas in the Scandinavian TIPS study have been followed for more than 20 years with symptom and functional measures. Assessments have taken place at inclusion, one, two, five, ten and twenty years. At the 20-year follow-up, 43% of living participants were retained; 15% had died.
Results: Data analysis is in progress, and symptoms and function results will be presented.

Disclosure of Interest: None Declared

Brain developmental trajectories in offspring of parents with severe mental illness

N. van Haren[1,2*] and DBSOS working group

[1]Child and adolescent psychiatry/psychology, Erasmus MC, Rotterdam and [2]Psychiatry, UMC Utrecht, Utrecht, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.134

Abstract: Early diagnosis and intervention are essential for managing and improving long-term outcomes of severe mental illness, highlighting the need for reliable early biomarkers. This longitudinal study explores whether there are sex differences in the development of the brain during childhood and adolescence differs between offspring of parents with and without a diagnosis in the mood-psychosis spectrum.
We obtained 286 T1-weighted and diffusion weighted MRI scans of 184 offspring (aged 8–18 years at baseline) of at least one parent diagnosed with bipolar disorder (n=78) or schizophrenia (n=52) and offspring of parents without severe mental illness (n=54); 102 offspring underwent a follow-up scan (on average 3.9 years between scans). Global brain measures, regional cortical thickness and surface area, gyrification and sulcul morphology were computed. Anatomical brain networks were reconstructed into structural connectivity matrices. Network analysis was performed to investigate anatomical brain connectivity. Group comparisons and the interaction with age were analysed with (non)linear mixed-effects models. Explorative analyses will be done on the interaction with sex. To correct for multiple comparisons, we applied a Benjamini-Hochberg false discovery rate (FDR) correction (q=0.05).
A significant effect of age was found on most of the included brain features, with suggestive evidence for subtle deviations in trajectories in the cortical thickness and network metrics, but not in the gyrification index and sulcul morpholoy in offspring of parents with schizophrenia. Sex effects will be discussed during the meeting. Our findings suggest the brain development in familial high-risk youngsters is associated with being at familial risk for schizophrenia.

SP053

Integrating Biological Sex in Precision Psychiatry: The advantage of Using Machine Learning for Personalized Care

M. F. Urquijo

Dept. for Psychiatry and Psychotherapy, LMU Hospital, Munich, Germany
doi: 10.1192/j.eurpsy.2025.135

Abstract: Sex differences in psychiatric disorders are well-documented, yet clinical diagnoses remain primarily symptom-based, overlooking underlying neurobiological distinctions. Despite evidence of sex-specific symptomatology leading to similar diagnostic labels, treatment paradigms often follow a one-size-fits-all approach, contributing to misdiagnosis, suboptimal treatment, and delayed functional recovery. Women, in particular, are disproportionately affected, as psychiatric research has historically prioritized male cohorts to control for hormonal fluctuations and reproductive events (e.g., menarche, pregnancy, menopause), resulting in a gap in sex-specific interventions.
With the advancement of precision psychiatry, integrating sex-informed, multimodal approaches into clinical decision-making is imperative. Machine learning (ML) provides a promising avenue for improving diagnostic accuracy and individualized risk prediction, moving beyond conventional categorical diagnoses.
Here I will highlight findings from two studies leveraging ML to analyze sex-related neuroanatomical patterns:

Neuroanatomical Sex Differences in Early-Phase Psychiatric Disorders – Investigating grey matter volume alterations in individuals at clinical high risk for psychosis (CHR), recent-onset psychosis (ROP), and recent-onset depression (ROD) using a Support Vector Machine (SVM) model.
Sex Differences and Neuroanatomical Classification in Transgender Individuals – Exploring whether ML classifiers trained on cisgender populations accurately reflect neurobiological patterns in transgender individuals, considering sex assigned at birth, gender identity, and hormone therapy.

This research does not seek to exclude individuals with Differences in Sex Development (DSD) but rather aims to establish biological sex as a critical, yet underutilized, variable in psychiatric research. Recognizing sex-specific neurobiological mechanisms is a necessary step toward developing targeted risk calculators (e.g., for postpartum depression, suicide risk) and advancing personalized mental health interventions. By refining ML-based models and integrating sex-informed frameworks, this work contributes to the broader goal of precision psychiatry—tailoring psychiatric care to the diverse biological and psychological realities of individuals.

Interplay among sex, environment, and heart-brain function in the onset of psychiatric disorders

E. Maggioni[1,2*] and P. Brambilla[1,3]

[1]Dept. of Neurosciences and Mental Health, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico; [2]Dept. of Electronics Information and bioengineering, Politecnico di Milano and [3]Dept. of Pathophysiology and Transplantation, University of Milan, Milan, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.136

Abstract: Despite the crucial need for objective diagnostic procedures in psychiatry, the research of the quantitative neural bases of mental disorders is in its infancy, and currently there are no well-validated markers that could be translated into clinical practice. Candidate brain markers for neurodevelopmental, psychotic, and mood disorders have been proposed, but confounding factors and low statistical power leave most of these markers at the very early stage of development. Increasing evidence suggests a crucial role of biological, especially including sex, and environmental factors in shaping behavioral development and psychopathological risk. Moreover, such risk seems associated with greater susceptibility to cardiovascular problems, possibly mediated by alterations in the brain-heart axis. In this context, the study of brain maturation trajectories and brain-heart interactions in relation to sex and environment can provide key insights on the etiology of complex mental illnesses.
This lecture will provide an overview of our recent research on the interactions among biological factors, in particular sex, environmental risk, brain morphology and function, and cardiac autonomic regulation in affective and psychotic disorders using multivariate analysis approaches. Evidence obtained from juvenile cohorts, including samples of twins, will be presented to provide useful information on the genetic and environmental determinants of behavioral developmental trajectories, and on sex differences in these trajectories. The complex relationships among sex, environmental risk, autonomic regulation, brain morphology and connectivity, and mental and physical health will be explored in transdiagnostic samples of young adults and elders. Special focus will be given to sex-shared and sex-specific brain and autonomic mechanisms affected by social stressors, including discrimination, bullyism, and chronic stress, and their possible role in determining the heterogeneous clinical dimensions of psychotic and affective disorders.

Update Gender Affirming Care in Adolescents with Gender Incongruence – Evidence Review and Clinical Implications Considering new Guidelines in different European Countries

D. Pauli

Child and Adolescent Pychiatry, Psychiatric University Hospital Zurich, Zurich, Switzerland
doi: 10.1192/j.eurpsy.2025.137

Abstract: Recently, there have been wide-ranging debates about gender affirming treatment for young people with gender incongruence. The ethical principle of self-determination of young people must be reconciled with a careful assessment and weighing up of the risks and benefits of medical treatment steps. The focus is on psychosocial support for young people struggling with gender incongruence in adolescence. The evidence for the effectiveness of medical interventions in adolescence is still limited. Nevertheless, there is a great need among affected adolescents. In a literature review and based on international debates, guidelines and treatment recommendations, a cautious and balanced approach to the question of the right support for adolescents with gender dysphoria is recommended.

Difficulties in implementing best standards in transgender mental health care in different European countries

K. Başar

Psychiatry, Hacettepe University, Ankara, Türkiye
doi: 10.1192/j.eurpsy.2025.138

Abstract: For decades, the standards of gender-related healthcare provided to trans and gender-diverse people have been prepared by international professional associations. These standards are often expected to rely on research evidence, but when the research evidence is not conclusive, an expert consensus is sought. In addition to the standards and guidelines updated with intervals, such as the Standards of Care for the Health of Transgender and Gender Diverse People, Version 8, and the Endocrine Treatment of Gender-Dysphoric/Gender-Incongruent Persons: An Endocrine Society Clinical Practice Guideline of the Endocrine Society, there are several national guidelines developed by the professionals in some European countries. There are significant similarities among these care principles concerning practical recommendations. However, the practice may vary depending on the differences in healthcare delivery systems and, more importantly, legal regulations. In general, international guidelines provide room for flexibility in practical applications. Yet, in recent years, there has been a significant change in many European countries with respect to the public appreciation of gender diversity and gender-related healthcare, mainly resulting from a politicized debate triggered by more conservative arguments rather than evidence. This backlash, which has also had a profound impact on the medical professional sphere, is a cause for concern. In this climate, it is becoming more challenging to develop and implement the standards of care for trans and gender-diverse individuals in many countries. Similarities of challenges in the implementation of standards also exist in the means of handling these challenges.

Necessity and Problems of Cooperation of Mental Health Professionals and Somatically Oriented Doctors in Gender-affirmative Healthcare

M. Van Trotsenburg[1,2]

[1]Consultancy genderPRO and [2]Sigmund Freud Private University Vienna, Vienna, Austria
doi: 10.1192/j.eurpsy.2025.139

Abstract: Multidisciplinary cooperation is an imperative prerequisite for good clinical practice in general, and for healthcare of gender-variant people in particular. Although self-determination of one's gender identity is regarded a human right and self-medication in the trans community widespread, gender-affirmative treatment (GAT) with its far-reaching consequences (including reimbursement by social insurances) still is based upon diagnostics – and more importantly – by indication of mental health professionals (MHP). Empathy and affirmative encounter cannot detract from the fact that medical interventions in general cannot be carried out without a diagnosis. It is the assignment and duty of MHPs to make a diagnosis of gender incongruence or gender dysphoria prior to GAT carried out by somatically oriented doctors. This mutual dependency is a constituent of transgender healthcare, not only at the beginning of a transition trajectory but life spanning. Mental and somatic health care are interdependent. Gender affirmative hormonal treatment and its potential side-effects as well as surgical intervention and its potential complications may have large impact on mental health, and vice versa mental health disorders impact medical conditions. MHPs and somatically oriented doctors are socialized and trained in different ways, sometimes complicating understanding. This presentation deals with the needs, peculiarities and obstacles of joint mentoring gender-variant patients from a medical perspective, not only at the beginning of transition but also in times of crisis or in the course of getting older.

Mental Health of Adolescents Exposed to the War in Ukraine

N. Skokauskas

NTNU, Trondheim, Norway
doi: 10.1192/j.eurpsy.2025.140

Abstract: This presentation will provide an overview of our original studies focusing on the mental health impact of the ongoing war in Ukraine on adolescents. Our studies address critical areas such as posttraumatic stress disorder (PTSD), anxiety, depression, suicidality, and the prevalence of psychiatric conditions, alongside resilience factors among war-affected youth. By synthesizing findings from the studies , the presentation will hilight the substantial psychological burden of the conflict on Ukrainian adolescents and emphasizes the pressing need for targeted mental health interventions. These studies contribute essential insights into the long-term implications of trauma, resilience, and mental health outcomes in conflict-affected populations, informing both research and clinical practice.

Current research school activities and strategies for the future

I. Agartz[1,2,3]

[1]Clinical Medicine, University of Oslo; [2]Department of Psychiatric Research, Diakonhjemmet Hospital, Oslo, Norway and [3]Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden
doi: 10.1192/j.eurpsy.2025.141

Abstract: It is important to support the Ukrainian mental health research and practice in time of war and after the war has ended. Norwegian universities engage in this by collaboration in psychiatric research and mental health initiatives.
With a grant from the University of Oslo and in collaboration with the Taras Shevchenko National University Kyiv, the Ukrainian Psychiatric Association, and the Norwegian Psychiatric Association, we launched a research school for young psychiatry and psychology researchers who are based in the Ukraine and who can travel outside the country. The research school and training class was held in Warsaw 2023, Krakow 2023 and in Oslo 2024. It offered scientific lectures, interaction with international researchers, and clinical site visits. The young Ukrainian researchers present their projects from early to completed phase to be openly discussed. Networking and scientific exchange is encouraged. The Oslo university library has opened their doctoral educational programs for Ukrainian doctoral students and the University of Oslo sponsors participation in international conferences.
We now aim for a renewed strategy to help meet the needs of mental health and clinical research in the Ukraine also after the end of the war.

SP060

Mental Health of University Students During and After the War: Battle for Ukrainian Future

V. Seleznova

Economics, Taras Shevchenko National University of Kyiv, Kyiv, Ukraine
doi: 10.1192/j.eurpsy.2025.142

Abstract: Objective: The study aims to analyze the mental health conditions of Ukrainian university students during and after the war and to examine the impact of these conditions on their academic productivity.
Methods: The research combines methods of cross-sectional surveys and regression analysis. The survey includes a demographic section, a mental health screening, and the "Work Productivity and Activity Impairment: Specific Health Problem" (WPAI: SHP) section, adapted for the study's purposes. The sample consists of 1,398 respondents.
Results: Among all respondents, 85.8% exhibited symptoms of depression, 66.1% of anxiety disorder, 56.9% of sleep disorders, and 48.1% of post-traumatic stress disorder (PTSD). Econometric modeling results confirm the devastating impact of mental health issues on students' academic productivity during the war: moderate to severe symptoms of mental disorders, such as

depression, anxiety disorder, and sleep disorders, are associated with a decline in students' productivity by 17.4%, 12.2%, and 11.0%, respectively.
Conclusion: The prevalence of mental health issues among university students during and after the war highlights an urgent need for interventions to support their well-being and academic performance. These efforts are critical for fostering a resilient and capable generation essential for Ukraine's postwar recovery and future development.
Keywords: Mental health, mental conditions, war, academic productivity, students.

Inflammatory Factors in Early Stages of Psychosis

A. Catalan

OSI Bilbao-Basurto, Bilbao, Spain
doi: 10.1192/j.eurpsy.2025.143

Abstract: Growing evidence suggests that inflammation plays a critical role in the early stages of psychosis, potentially contributing to disease onset and progression. Several studies have identified elevated levels of pro-inflammatory cytokines, such as interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF-α), in individuals at clinical high risk (CHR) for psychosis and in those with first-episode psychosis (FEP). However, inconsistencies across studies highlight the need for further research to clarify the relationship between immune dysregulation and psychosis onset.
This talk reviews the current literature on inflammatory markers in early psychosis and their potential implications for pathophysiology, early detection, and treatment strategies. Notably, inflammation may serve as a promising biomarker for identifying individuals at risk and monitoring disease progression. Additionally, anti-inflammatory interventions are being explored as potential adjunctive treatments for psychosis.
Beyond the review of existing evidence, we will present **original data** from the **PREGAP study** conducted at the **Early Intervention \Service (EIS) of Basurto University Hospital**. This dataset includes inflammatory marker assessments in CHR and FEP individuals, providing novel insights into immune alterations in early psychosis. Understanding the role of inflammation in psychosis could open new avenues for personalized medicine, early intervention, and improved treatment outcomes. Future research should focus on large-scale longitudinal studies to confirm the clinical utility of inflammatory markers and identify potential therapeutic targets.

Compulsivity and Treatment Resistant Schizophrenia

E. Fernández-Egea

University of Cambridge, Cambridge, United Kingdom
doi: 10.1192/j.eurpsy.2025.144

Abstract: Obsessive-compulsive symptoms (OCS) are a prevalent and under-recognized complication of clozapine treatment in schizophrenia, with significant implications for clinical practice and patient outcomes. This synthesis of four longitudinal studies explores the interplay between psychosis, clozapine dose, and OCS, emphasizing their phenomenology, prevalence, and impact.
OCS, particularly checking compulsions, affect up to 47% of clozapine-treated patients, with risk factors including psychosis severity, duration of clozapine therapy, and antiserotonergic properties of the drug. A two-phase model of OCS development is proposed: during active psychosis, compulsions emerge as goal-directed responses to hypervigilance, while post-remission, they persist as maladaptive habits mediated by clozapine's serotonergic effects. While clozapine improves psychotic symptoms, its dose and plasma levels are positively correlated with OCS persistence after psychosis remission, suggesting a dose-dependent effect.
Notably, OCS significantly reduce subjective well-being independently of depressive and psychotic symptoms but do not impair general functioning, highlighting the ego-syntonic nature of compulsions. Screening for and addressing OCS in clinical practice is critical for optimizing therapeutic outcomes.
This integrated perspective advances our understanding of the nuanced relationship between schizophrenia, clozapine treatment, and OCS, with implications for personalized treatment strategies.

SP063

Mind Altered, or calmed down: the enigma of substance use and psychosis

A. Batalla

UMC Utrecht, Utrecht, Netherlands
doi: 10.1192/j.eurpsy.2025.145

Abstract: Cannabis use is highly prevalent among individuals at risk for psychosis, yet its role remains paradoxical—offering both temporary relief and potential harm. In this session, we present preliminary results from a study examining cannabis perception, use patterns, and motivations in cannabis users with and without psychosis. Findings reveal that cannabis users with psychosis consume over three times more THC but do not perceive significantly greater risks. They also exhibit a higher risk of cannabis addiction, which may influence their risk assessment and experience of cannabis effects. Both groups reported similar reasons for use and quitting, though individuals with psychosis were more likely to cite cost as a reason for quitting. These insights suggest that financial concerns could be a target for intervention.

Understanding why individuals vulnerable to psychosis turn to substances is crucial for refining treatment strategies, as addressing these underlying motivations may enhance therapeutic outcomes.

Recent progress in women's mental health research and future priorities

F. Thibaut[1,2,3]

[1]Psychiatry and Addictive Disorders, University Paris Cité; [2]Psychiatry and Addictive Disorders, University Hospital Cochin and [3]INSERM U1266, Institute of Psychiatry and Neurosciences, Paris, France
doi: 10.1192/j.eurpsy.2025.146

Abstract: Introduction: Women face a greater incidence of mental health issues than men, stemming from societal expectations, gender stereotypes, organizational structures that prioritize male leadership, and the need to balance work responsibilities with home life. Research indicates that women are twice as likely to suffer from depression, generalized anxiety disorder, and post-traumatic stress disorder (PTSD) compared to men. They are also more likely to battle eating disorders.
Methods: The authors will review the current literature on this topic.
Results: 43% of female executives experience burnout, compared to 31% of their male counterparts (Mc Kinsey 2024). Research is definitely needed to better understand the pathophysiology and socioeconomic mechanisms that drive sex-specific risk factors of psychological disorders in women. There is also an urgent need for studies that addressed the specific needs of women including insights around: the biological, life stage, socioeconomic, political and cultural factors associated with being female that have a significant impact on women's mental health.
Conclusion: A mental health reform is necessary to prevent mental illnesses in women, provide specific care to vulnerable women and increase the overall well-being of women living with existing mental health conditions.

Health records 'big data' in mental health research – should 'Clinical Informatics' be considered a discipline within Epidemiology?

R. Stewart

King's College London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.147

Abstract: Background: Traditionally, the discipline of Epidemiology, regardless of clinical specialty, has tended to focus on public health in community populations, although its study designs are widely applied in more clinically oriented research. The emergence and rapid accumulation of digital health records have resulted in data resources that are both large in sample size and granular in detail presenting unprecedented opportunities for understanding course and outcome in mental health.
Methods: Drawing on over 15 years of experience in building and achieving research output from electronic mental health records data in south London, this presentation will consider the role of Epidemiology as a discipline in this field.
Results: There is no fundamental difference between studying disease incidence in community populations and using healthcare data to study disease course and outcome in clinical populations, and there are similar considerations of sample representativeness and cohort cohesion. Psychometrics principles are also strongly applicable to measurement issues in clinical data, although computer science collaborations particularly underpin the natural language processing and m-health advances required to improve information availability in routine data. Clinical Informatics and Epidemiology face common analytic challenges from data density and complexity, as well as in realising novel clinical trials opportunities.
Conclusions: Clinical Informatics does benefit from the public health focus that Epidemiology brings, as well as its methodological frameworks. However, multiple disciplines are key to setting up and maintaining data resources and achieving research output, so it is equally important to flatten hierarchies and enable a genuine cross-cutting team science approach.

Anxiety and depression in young people in the UK: demographic differences and growing treatment gaps

J. Dykxhoorn

Division of Psychiatry, UCL, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.148

Abstract: Background: Rates of common mental disorders (CMD), such as anxiety and depression, treated in primary care have increased among young adults in the UK. However, it remains unclear whether this increase reflects a greater tendency to seek help for CMD or a rise in CMD symptoms over time. Additionally, it is not clear if these increases are more pronounced in specific sociodemographic groups. This research examined the temporal trends of primary care-recorded CMD and self-reported CMD symptoms in young adults.
Methods: We included participants born between 1980 and 2003 in two datasets: UK primary care records from the *Clinical Practice Research Datalink*, and longitudinal cohort data from *Understanding Society*. We estimated the annual incidence of primary care-recorded CMD overall and by sex, age, birth cohort, ethnicity, country, region, and deprivation from 2009 to 2019, and explored changes over time using incidence rate ratios. We compared these trends to annual estimates of self-reported CMD symptoms from longitudinal cohort data between 2009-10 and 2019-20, calculating ratios to explore changes in CMD symptoms over time by sociodemographic group.

Results: Between 2009 and 2019, the incidence of recorded CMD increased by 9·90% and CMD symptoms increased by 19·33%. The sharpest increases for both recorded CMD and CMD symptoms were observed in older adolescents (ages 16-19) and those born after 1995. Recorded CMD increased more in males (20·61%, increase) than in females (7·65%), despite similar increases in CMD symptoms. Recorded CMD increased the most in the least deprived areas of England (16·34%) compared to the most deprived areas (3·55%), despite similar increases in CMD symptoms across all levels of deprivation.
Conclusions: Both primary care-recorded CMD and self-reported CMD symptoms in young adults increased between 2009-19, suggesting that the rising rates of CMD treated in primary care may reflect heightened symptoms of CMD. However, differences in the patterns of recorded CMD and CMD symptoms across sociodemographic groups highlight potential misalignment between mental health care provision and underlying population need, suggesting that the groups with the highest burden of CMD symptoms may not be the groups most likely to receive care.

Psychosocial functioning in offspring of parents with bipolar and unipolar mood disorders assessed across 15 years of follow-up

M. Preisig

Psychiatry, Lausanne University Hospital and University of Lausanne, Lausanne, Switzerland
doi: 10.1192/j.eurpsy.2025.149

Abstract: Objective: High-risk studies have shown significant parent-child transmission of bipolar disorders (BPD) and major depressive disorder (MDD), which was stronger when parents had a mood disorder with an early onset. However, less studies have focused on functional outcomes of these offspring across development and most studies have not adjusted for the effect of offspring psychopathology. Our goal was to assess 1) psychosocial functioning in offspring of parents with mood disorders, and 2) the role of emerging mood psychopathology in offspring on the association between the parental mood disorder and psychosocial functioning in offspring.
Methods: We have collected clinical information on 32 patients with early-onset BPD (prior to age 21), 54 with later-onset BPD, 23 with early-onset MDD, 51 with later-onset MDD, 74 controls and their 425 offspring assessed for a mean duration of 14.9 (s.d: 5.3) years. Current Global Assessment of Functioning (GAF) scores for offspring were rated by trained interviewers after administering diagnostic interviews. Multilevel models adjusting for intra-familial correlation (several offspring per family) assessed the impact of parental mood disorders on the last rated GAF scores for offspring, with and without adjustment for offspring mood disorders over the follow-up.
Results: An initial model showed an association between early-onset BPD and a trend level association between early-onset MDD in parents with lower GAF scores in offspring. However, these associations disappeared after adjustment for emerging offspring mood disorders.
Conclusion: Our data suggest that the frequently reported lower psychosocial functioning in high-risk offspring is essentially mediated by emerging offspring mood psychopathology.

Disclosure of Interest: M. Preisig Grant / Research support from: This research was and is supported by five grants from the Swiss National Foundation (SNF: #3200-040677, #32003B-105969, #32003B-118326, #3200-049746 and #3200-061974), three grants for a National Centers of Competence in Research project "The Synaptic Bases of Mental Diseases" (#125759, #158776, and #51NF40 – 185897) financed by the Swiss National Foundation, one grant from the Swiss State Secretariat for Education, Research and Innovation (SERI #22.00170), one grant from the Foundation Campus Biotech Geneva, and one grant from GlaxoSmithKline Clinical Genetics. The funders had no involvement in any aspect of this study.

Alcohol and nicotine: quitting both or keep smoking?

G. Dom

University of Antwerp, Antwerp, Belgium
doi: 10.1192/j.eurpsy.2025.150

Abstract: people with alcohol- and substance use disorders have disproportionally high levels of tobacco use compared with the general populations. This concerns not only the prevalence of nicotine dependence but also the intensity of their smoking behaviour. Importantly, regarding the negative consequences the combined effects of alcohol and smoking are exponentially. Efforts to include smoking cessation treatment within the treatment programs for AUD and other SUD patients need to be intensified.

Disclosure of Interest: None Declared

Implementation of feasible health care services for smoking cessation in persons with mental illness – barriers and facilitators

A. Høye[1,2*] on behalf of CVD-MENT Norway

[1]Department of Clinical Medicine, UiT The Arctic University of Norway and [2]Division of Mental Health and Substance Abuse, University Hospital of North Norway, Tromsø, Norway
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.151

Abstract: Introduction: Smoking remains a significant cause of mortality and morbidity, with a higher prevalence among those with severe mental illness compared to the general population. Patients with psychotic disorders are the most frequent smokers, which contributes to increased somatic diseases and cardiovascular

risk. Existing guidelines for smoking cessation are not well-suited for patients with mental disorders, and these patients often lack confidence in their ability to quit. An effective intervention must therefore be comprehensive and interdisciplinary to increase motivation. As part of the national, Norwegian multicenter project "Preventing Multimorbidity in Severe Mental Disorders with a Multidisciplinary Approach (CVD-MENT), the subproject *User-Driven Smoking Cessation Group* has been launched. The idea of users' active participation as co-leaders of a smoking cessation group comes from patients and is based on their experiences with their own smoking cessation attempts.

Objective: To investigate whether a new, tailored treatment specifically targeted at patients with severe mental disorders affects smoking behaviour in a patient group known to have a very high risk of cardiovascular disease.

Materials and methods: The program for the User-Driven Smoking Cessation Group is based on the existing template for smoking cessation groups described by the Norwegian Directorate of Health, but is adapted to the patient group. The study is conducted at three Norwegian hospitals. International recommendations for smoking cessation counselling describe the approach to unmotivated and ambivalent participants in five R's, all of which are emphasized in the project:

- Relevance - Help the patient reflect on whether tobacco cessation might be relevant
- Risks - Discuss personally related health risks
- Rewards - Help the patient articulate potential benefits of quitting tobacco
- Roadblocks - Identify barriers preventing the patient from attempting to quit
- Repetition - Prepare the patient for discussing this again at the next meeting

The project has developed a program for open smoking cessation groups specifically tailored for individuals with severe mental disorders. Patients who have successfully quit smoking actively participate in leading the group alongside healthcare professionals. The content focuses on smoking cessation, but other factors known to impact cardiovascular risk are addressed in the semi-structured teaching over seven sessions. Training is provided for users who are co-leaders.

Conclusion: Experiences from a pilot study and preliminary experiences and results from the first groups will be presented and discussed.

The Lancet Psychiatry Commission on Transforming Mental Health Implementation Research

E. Mcginty

Health Policy & Economics, Weill Cornell Medicine, New York, United States
doi: 10.1192/j.eurpsy.2025.152

Abstract: While many evidence-based mental health prevention, promotion, and treatment interventions exist, they are poorly and inequitably scaled across populations. Too often, research produces interventions and implementation strategies that are difficult to scale due to misalignment with culture, policy, system, community, provider, and individual realities. This presentation will introduce the Lancet Psychiatry Commission on Transforming Mental Health Implementation Research, which makes five recommendations to transform the research enterprise to produce more actionable evidence and address the mental health implementation gap. These recommendations focus on strategies for integrating research and real-world implementation; centering health equity in mental health intervention and implementation research; using a complexity science lens to study strategies for scaling effective interventions; expanding research designs beyond the traditional randomized clinical trial; and using transdisciplinary approaches. The Commission also made cross-cutting recommendations related to elevating work on mental health systems and policy and the importance of strengthening mental health implementation research globally.

Implementing Cognitive Remediation Therapy (CRT) in the routine treatment of schizophrenia

T. Wykes on behalf of Matteo Cella and Rumina Taylor

Psychology, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.153

Abstract: ***Background:*** Despite rigorous evidence of the benefits, costs and savings and mentions in treatment guidance, cognitive remediation access is still sparse. Providers are often confused by disagreements about the strength of the benefits evidence, some think it is a game not a treatment and others do not consider that cognition should be a treatment target. These are all issues that were present in the literature at least ten years ago.

Aim: To identify the steps to widespread implementation of this beneficial intervention

Method: Drawing on the literature and data from a large UK adaptive randomised control trial, we describe three: (i) the barriers and facilitators for the implementation into first episode services, (ii) cost effectiveness and (iii) training rollout and competency.

Results: (i) Clinicians need to understand the relevance of cognition and be aware of effective interventions, (ii) Despite evidence of efficacy a therapist seems important for engagement and leads to cost effective therapy and (iii) online therapy can improve competencies for delivering cognitive therapy and but commitment to completing therapy is related to management commitment.

Conclusion: All the implementation issues can be overcome but we still need to understand the non-specific effects of cognitive remediation as well as the specific if we are to provide a formulation-based approach. Clinicians need to know that cognitive remediation is not "brain training" but is a holistic therapy that involves an active therapist providing motivation support, and who helps to mitigate the impact of cognitive difficulties through metacognition to develop awareness of cognitive approaches to problems.

Assessment and Management of PTSD Among Children and Adolescents with ADHD as a Preventive Strategy for Suicidal Behaviours

H. Kerbage[1,2]

[1]Developmental Psychiatry Team, Center for Epidemiology and Population Health (CESP) INSERM U1018, Paris-Saclay University, Paris and [2]Department of Child and Adolescent Psychiatry, Montpellier University Hospital, Montpellier, France
doi: 10.1192/j.eurpsy.2025.154

Abstract: Children and adolescents with Attention-Deficit/Hyperactivity Disorder (ADHD) are at an increased risk of experiencing traumatic events and developing Post-Traumatic Stress Disorder (PTSD). The interplay between ADHD and PTSD presents unique diagnostic and therapeutic challenges, as symptoms such as emotional dysregulation, impulsivity, and attentional difficulties may overlap, complicating early identification and intervention. Notably, the presence of both ADHD and PTSD significantly heightens the risk of suicidal spectrum behaviors, underscoring the need for targeted clinical strategies. This presentation will explore current evidence on the association between ADHD, PTSD, and suicidal behaviors in youth, highlighting the neurobiological, cognitive, and psychosocial mechanisms that contribute to this heightened vulnerability. We will discuss practical approaches for screening PTSD in children and adolescents with ADHD, considering both clinical and psychometric tools tailored to this population. Additionally, we will examine intervention strategies that integrate trauma-focused care within ADHD management, including psychoeducation, cognitive-behavioral therapy (CBT), parent training, and pharmacological considerations.

The interplay between ADHD comorbid bipolar disorder and suicide behavior

R. J. Bou Khalil[1,2,3]

[1]Psychiatry, Hotel-Dieu de France hospital; [2]Psychiatry, Saint-Joseph university and [3]Lebanese Psychiatric Society, Beirut, Lebanon
doi: 10.1192/j.eurpsy.2025.155

Abstract: This presentation examines the complex relationship between Attention-Deficit/Hyperactivity Disorder (ADHD) and bipolar disorder in the context of suicide risk. A comprehensive literature review will first explore existing studies on the interplay between ADHD, bipolar disorder, and suicidal behavior in youth. In addition, a retrospective analysis of clinical data extracted from a large database at Hôtel-Dieu de France Hospital in Beirut will be presented. The ongoing study includes approximately 700 patient files and aims to evaluate the suicide risk over the past three years, specifically assessing the role of ADHD vulnerability and a history of hospitalization for mood disorders. The analysis will explore whether the increased suicide risk in individuals with ADHD is primarily attributed to comorbidity with bipolar disorder or inherent aspects of ADHD itself. The presentation will provide insights into the underlying pathophysiology, offering a deeper understanding of these critical associations, and will discuss implications for clinical risk assessment and intervention strategies.

Emotional dysregulation and Non Suicidal Self Injury in adolescents with ADHD transitioning to young adulthood

S. Marchini[1,2]

[1]Faculté de Médecine, Université Libre de Bruxelles and [2]Service de Psychiatrie de l'Enfant et de l'Adolescent, Hôpital Universitaire de Bruxelles, Brussels, Belgium
doi: 10.1192/j.eurpsy.2025.156

Abstract: Non-suicidal self-injury (NSSI) is a significant public health issue, particularly among adolescents with attention-deficit/hyperactivity disorder (ADHD). Characterized by inattention, hyperactivity, and impulsivity, ADHD is strongly linked to emotional dysregulation (ED) and psychiatric comorbidities, exacerbating vulnerability to self-injurious behaviors. This presentation examines the relationship between ADHD, ED, and NSSI, emphasizing clinical strategies for assessment and intervention during adolescence and the transition to adulthood.

Adolescents with ADHD often struggle with heightened emotional sensitivity and impaired emotion regulation, which can lead to NSSI as a maladaptive coping mechanism. ED mediates the connection between ADHD symptoms and NSSI. Evidence suggests that individuals with persistent ADHD and ED are at increased risk of psychiatric comorbidities such as depression, anxiety, and borderline personality disorder—factors independently associated with NSSI and suicidal behaviors (SB). Key findings include:

- ED and impulsivity contribute to risk-taking behaviors, poor decision-making, and increased vulnerability to NSSI.
- NSSI often begins in early adolescence and can escalate to severe SB, especially in individuals with co-occurring depression or adverse childhood experiences (ACE).
- Girls with ADHD show higher rates of NSSI, often mediated by comorbid conditions such as depression and substance use disorders, underscoring the need for gender-specific interventions.

Cheng et al. (2024) demonstrated that ADHD subtypes marked by inattention were more associated with NSSI than hyperactivity/impulsivity, with anxiety as a significant mediator, especially for females. Ojala et al. (2022) found that childhood inattention predicts mid-adolescent NSSI, underscoring the importance of early detection. Balázs et al. (2018) highlighted the mediating roles of affective and psychotic disorders, with alcohol abuse uniquely influencing girls. Thornton et al. (2024) emphasized the role of cognitive disengagement syndrome (CDS) in predicting self-injurious behaviors.
These findings support integrating emotional regulation therapies into ADHD treatment frameworks. Interventions such as Dialectical Behavior Therapy (DBT), emotion-focused therapies, and ADHD medications addressing ED can mitigate risks of NSSI. Early identification and tailored care strategies targeting inattention and comorbid conditions are critical. Clinicians should screen for ADHD in adolescents presenting with NSSI and vice versa to ensure comprehensive treatment.
This presentation highlights the urgent need for developmentally sensitive approaches to mitigate NSSI risks in adolescents with ADHD, particularly during the vulnerable transition to adulthood. Addressing ED offers a promising avenue for reducing self-injury and improving psychosocial outcomes.

Catching met- and unmet care needs in real-world catchment area: the Antwerp experience

G. Dom

University of Antwerp, Antwerp, Belgium
doi: 10.1192/j.eurpsy.2025.157

Abstract: Increasingly the collection and use of clinical data is considered as extremely important. These data may allow, among other targets, a better profiling of patients and as such help to develop better and more targeted care-pathways. Often these type of data collections are implemented on large, national levels. Although this already provides an important source of information, often the regional specifics are missed on these larger scales. Within the Antwerp region we developed a program allowing a deeper, smaller grained, level analyses of populations mental health care needs and their regional differences. The aim is to use these data to steer changes in the care pathways as offered by the different locally active care-providers.

Dealing with Dementia: Insights from the Latest German Guidelines

J. Benninghoff

Zentrum für Altersmedizin und Entwicklungsstörungen - ZfAE, kbo, München, Germany
doi: 10.1192/j.eurpsy.2025.159

Abstract: The management of Behavioral and Psychological Symptoms of Dementia (BPSD) remains a key challenge in clinical practice. This presentation will provide an overview of the latest German guidelines, highlighting evidence-based recommendations for pharmacological and non-pharmacological interventions. Key updates emphasize a patient-centered approach, focusing on prevention, risk assessment, and the integration of innovative care strategies. By examining these guideline revisions, the session aims to equip healthcare professionals with practical insights to optimize dementia care and improve patient outcomes in line with current best practices in Germany.

How to manage Depression in Dementia and Parkinson's Disease: A Spanish Consensus

L. Aguera-Ortiz

Psychiatry, University Hospital 12 de Octubre, Madrid, Spain
doi: 10.1192/j.eurpsy.2025.160

Abstract: Psychological and behavioural symptoms are an inherent part of neurodegenerative diseases such as Alzheimer's disease and other dementias or Parkinson's disease. Despite the growing research on the subject, there are still large gaps in knowledge about their origin, pathophysiology, diagnosis and treatment. In recent years, various initiatives have been carried out in Spain to improve knowledge, especially on the most controversial issues, of various

aspects such as Alzheimer's disease from the point of view of Psychiatry, the use of antipsychotic drugs or depression in neurodegenerative diseases. The presentation will include data on these national initiatives and will address in more detail two studies using Delphi methodology referring to depression in neurodegenerative diseases. The first one addressed depression in the context of Alzheimer's disease and other dementias in 53 controversial items regarding risk factors, signs and symptoms, diagnosis and treatment. The second one addresses depression in Parkinson's disease in 49 controversial issues about the aetiopathological mechanisms, clinical features and connections with motor and non-motor symptoms, diagnostic criteria, and therapeutic options. In both cases, in addition to trying to shed light on etiological and clinical aspects, specific advice is provided on the choice of antidepressant treatment and the particularities linked to its prescription.

Are New Technologies suitable for Real-World Management of Dementia?

R. David

Memory Clinic – Sport-related concussion - Old age psychiatry, CHU Nice – Université Côte d'Azur, Nice, France
doi: 10.1192/j.eurpsy.2025.161

Abstract: The management of dementia presents significant challenges due to the multifaceted nature of major neurocognitive disorders, encompassing cognitive impairments, behavioral and psychological symptoms, and loss of autonomy. Current strategies, including pharmacological and non-pharmacological approaches, have shown limited success, often hindered by adverse effects, lack of efficacy, and insufficient human resources. In this context, emerging technologies offer promising solutions for improving dementia care. Their potential benefits and limitations will be presented: Digital Solutions • Serious Games and Smart Apps: Digital tools can enhance cognitive function and support social engagement for individuals with dementia. Studies show that structured use of these technologies in home settings improves well-being and reduces isolation. Internet of Things (IoT) • Applications: IoT devices such as sensors, GPS trackers, cameras, and wearable technologies are increasingly used to monitor aspects of dementia care. These include activities of daily living (ADLs), sleep patterns, medication adherence, vital signs, and safety concerns like fall detection and wandering.

Inflammation in Bipolar depression: triggers and targets

M. Leboyer[1,2,3]

[1]Creteil, Paris Est University (UPEC); [2]Translational NeuroPsychiatry, INSERM and [3]Fondation FondaMental, Créteil, France
doi: 10.1192/j.eurpsy.2025.162

Abstract: Repeated reports of association of low-grade inflammation in bipolar disorder led to exploration of the causes and consequences of this inflammatory background, now thought to be due to interaction between environmental factors such as infections, stress, pollution, unhealthy life style with immune-genetic background.

Association with functional gene variants of Toll-Like Receptor genes (TLR, NOD), possibly explain diminished response to infections observed in bipolar disorder (rev in Oliveira et al, 2017) association while mitochondrial genes (Angrand et al, BBI, 2021), HLA-E and HLA-G (Boukouaci et al, 2021) contribute to maintenance of inflammation. Association with particular HLA haplotypes very likely explains pro inflammation and auto-immune induction observed particulary in bipolar patients with suicidal behavior and/or with rapid cycling (Tamouza et al, 2020). While HLA haplotypes, in particular when they are associated to anti-inflammatory effect have also been found to be associated with good lithium response (Leclerc et al, 2021).

Systemic inflammation and persistent infections activate different pathways paving the way to biomarker-guided personalized medicine. For example the identification of "autoimmune psychosis" defined by presence of anti-neuronal antibodies in psychosis and in bipolar disorder (Jezequel et al, 2017). Systemic inflammation induced by microbial infection and/or psychosocial factors can also be at the origin of the activation of human endogenous retrovirus (HERV-W) in patients with bipolar disorder (Tamouza et al, 2021).

One last example can be found in the immune-metabolic abnormalities that pave the way to metabolic syndrome associated with psychiatric disorders. Various mitochondrial dysfunctions have recently been reported including deregulated bioenergetics and mitochondrial DNA alterations in bipolar disorder, underlying depressive and manic episodes and their association with metabolic syndrome.

Findings accumulated so far favour the consideration of cellular and molecular targets for the treatment of specific subgroups of bipolar disorders. This is the case for clinical trials of the efficacy of anti-inflammatory treatment in patients with blood auto-antibodies against brain receptors. Or for low dose IL-2 therapy in bipolar depression based on the hypothesis that IL-2 is a differentiation factor for T cells and low dose IL-2 combats premature T cell aging and induce the production of new naïve T cells from the thymus particularly T regulator cells (Leboyer et al, 2025). Another example comes from drugs that boost mitochondrial function in bipolar depression (Khandra et al, 2023).

SP081

Immunometabolic function in depression: From etiology to treatment

B. Penninx

psychiatry, Amsterdam UMC, Amsterdam, Netherlands
doi: 10.1192/j.eurpsy.2025.163

Abstract: Background: Major depressive disorder is a common, disabling mental disorder characterized by extensive etiological and phenotypic heterogeneity. This heterogeneity makes treatment approaches imprecise and often ineffective. Insight into the underlying biological mechanisms underpinning depression and its subtypes may enable more personalized treatments.
Methods: A review of the literature as well as data analyses from 2981 individuals from the Netherlands Study of Depression and Anxiety (NESDA), of whom ˜1900 persons have or lifetime or current Major Depressive Disorder and 650 were healthy controls.
Results: Significant immuno-metabolic dysregulations are present in about 20-30% of people with depression. Such immuno-metabolic depression is characterized by the clustering of 1) atypical, energy-related depressive symptoms such as hypersomnia, fatigue, hyperphagia, and possibly anhedonia, 2) systemic low-grade inflammation with elevated levels of e.g. C-reactive protein, cytokines and glycoprotein acetyls, and 3) metabolic abnormalities involving e.g. obesity, dyslipidaemia, insulin and leptin resistance. Evidence for such clustering is confirmed in large-scale proteomic, metabolomic, gene expression as well as genome-wide data analyses. Persons with immuno-metabolic depression are at a higher risk for cardiometabolic diseases and – from pooled analyses of 4 RCTs in over 1000 individuals - seem to respond less well to standard antidepressant treatment.
Discussion: Interventions targeting inflammation, metabolism or lifestyle may be more effective treatment options for individuals with immuno-metabolic depression, in line with principles of precision psychiatry.

Advancing Biomarker Research in Depression: The role of neuroprotective and inflammatory markers

J. Eder[1], P. Falkai and POKAL Group

Department of Psychiatry and Psychotherapy, LMU University Hospital, Munich, Germany
doi: 10.1192/j.eurpsy.2025.164

Abstract: The search for biomarkers to diagnose depression is an endeavor being pursued in psychiatric research since the 1980s, but hasn't resulted in clinical application. This remains challenging since the symptomatology of depression is very heterogeneous and because there is no diagnostic gold standard that focuses on an underlying biological mechanism. Despite knowing about the metabolic, endocrine, inflammatory as well as autonomous dysregulation that has been observed in depressed patients, none of these are broadly used to stratify patients. A novel area of research involves the insulin-like growth factor (IGF) system, which plays a vital role in brain development, neurogenesis, and neuroprotection. The insulin-like growth factor (IGF) system, encompassing IGF-I, IGF-II, IGFBPs (1-6), and their receptors, is critical for brain development, neurogenesis, neuroplasticity, and neuroprotection. Insulin-like growth factor binding protein-2 (IGFBP-2), the predominant IGFBP in the central nervous system, regulates IGF-I and IGF-II bioavailability, half-life, localization, and receptor interactions. Serum levels of IGFBP-2 inversely correlate with DTI-derived myelin integrity measures, especially in anterior brain regions.
In a data-driven clustering analysis of a depressed cohort, elevated IGFBP-2 levels delineated a healthier subgroup within a hospitalized cohort of patients with unipolar depression. Additionally we discovered, that patients with higher IGFBP2 levels at inclusion were more likely to remit faster concerning their depressive symptoms, in contrast to an inflammatory marker-defined subgroup. These findings suggest IGFBP-2 as a biomarker for stratifying patients and tailoring interventions in depression. Future research should explore IGFBP-2 and inflammatory markers to better stratify patients and develop targeted therapies, advancing precision medicine for depression and related disorders.

State- versus trait- dependent immune alterations in major depression: Exploring CRP, numerical and functional changes in neutrophils and monocytes

J. Steiner

Psychiatry and Psychotherapy, University of Magdeburg, Magdeburg, Germany
doi: 10.1192/j.eurpsy.2025.165

Abstract: Background: Inflammatory processes and innate immune system activation have been implicated in psychiatric disorders. While our prior research highlighted elevated neutrophils, monocytes, and C-reactive protein (CRP) associated with symptom severity in schizophrenia, this study investigates whether similar immune alterations characterize major depression (MD).
Methods: Differential blood counts, CRP levels, depression severity (HAMD-21), and psychosocial functioning (GAF) were assessed in controls (n = 129) and patients with first-episode (FEMD: n = 82) or recurrent (RMD: n = 47) MD at hospital admission (T0) and after 6 weeks of treatment (T6). Functional immune parameters, including the phagocytic activity of neutrophils and monocytes, were also measured in a subset of patients with MD (n = 16) and healthy controls (n = 27).
Results: At T0, both FEMD and RMD patients exhibited increased neutrophils ($p = 0.034$) and CRP levels (FEMD: $p < 0.001$, RMD: $p = 0.021$) and decreased eosinophils (FEMD: $p = 0.005$, RMD: $p = 0.004$) compared with controls, adjusted for covariates (smoking, BMI, gender). Baseline lymphocyte counts were elevated in RMD ($p = 0.003$) but not FEMD. Functional analyses revealed significantly increased phagocytic activity of neutrophils in MDD

patients compared to controls, both at baseline and T6. Changes in monocyte phagocytic activity correlated with ΔHAMD, indicating a link between immune cell function and symptom improvement.
At T6, eosinophils increased in FEMD (p = 0.011) without significant changes in RMD. Improvement in depression severity correlated with changes in neutrophil counts in FEMD (r = 0.364, p = 0.024). Comparatively, immune alterations in MD showed smaller effect sizes than those observed in schizophrenia. Notably, lymphocyte elevations were specific to recurrent MD, suggesting potential involvement of adaptive immunity in chronic MD.
Conclusions: These findings highlight state- and trait-dependent immune alterations in MD, including heightened neutrophil activity in early stages and adaptive immune involvement in recurrent cases. Functional data further support the role of innate immune activation in MD, with phagocytic activity potentially serving as a biomarker for treatment response. Future studies may inform stage-specific immune-targeted interventions in MD.

The Association Between Childhood Maltreatment and Somatic Symptoms in Adulthood

A. M. Luond[1] and G. Ayas[2,3]

[1]Adult Psychiatry and Psychotherapy, University Hospital of Psychiatry, Zurich, Switzerland; [2]Graduate School of Health Sciences, Koc University and [3]Affective Laboratory, Koç University Research Center for Translational Medicine (KUTTAM), Istanbul, Türkiye
doi: 10.1192/j.eurpsy.2025.166

Abstract: Background: Childhood maltreatment (CM) encompasses various forms of abuse and neglect before age 18 and frequently manifests in somatic symptoms (SS) such as chronic pain or fatigue. Despite growing recognition of this connection, the relationship between specific CM types and SS, as well as the mechanisms underlying this link, remains incompletely understood.
Objective: To examine the current understanding of the association between CM and SS, to highlight gaps in the literature, and propose directions for future research.
Method: A state-of-the-art review searching a range of different databases was performed to explore the interplay between CM (exposure) and SS (outcome) in adults (over age 18).
Results: Identified literature gaps include 1) inconsistency regarding the specific impact of subtypes of CM, specifically of neglect, on the development of SS; 2) narrowing the focus to specific functional syndromes (e.g., fibromyalgia), or selected health outcomes (e.g., respiratory disease) rather than SS as a broad category; and 3) underexploring the impact of culture.
Discussion: Key recommendations for future research include adopting standardized WHO definitions for CM subtypes, expanding SS diagnostic criteria (e.g. through using comprehensive ICD-11 coding), and integrating cultural moderators (e.g. different health beliefs) into research methodologies. By adopting these recommendations, research could significantly improve patient care and mitigate the broader societal consequences of childhood trauma.

Psychotherapy training in Turkey and Europe, similarities and differences

E. Sönmez Güngör

Psychiatry, Erenköy Mental Health and Neurological Diseases Training and Research Hospital, Istanbul, Türkiye
doi: 10.1192/j.eurpsy.2025.167

Abstract: Evidence for efficacy of various modalities of psychotherapies is growing and such therapies are increasingly recommended in international guidelines for the treatment of psychiatric disorders. Psychiatrists with strong psychotherapy skills are better positioned to provide individualized and multidisciplinary care. Training in psychotherapy also fosters the development of reflective practice, empathy, and cultural competence, all of which are vital in addressing the diverse needs of patients. Accessibility of psychotherapeutic treatment for the patients can be improved through integrating psychotherapy training in psychiatric training, together with continuous medial education activities. European and other international organisations have published guidelines requiring programs to promote psychotherapeutic competences among psychiatry trainees. However, psychotherapy education and supervision can often become a luxury rather than being a mandatory component of training; and resources are heterogenous. In this presentation, psychotherapy training availabilities and limitations in Turkey will be discussed, with a focus on the psychotherapy courses of Psychiatric Association of Turkey among other initiatives.

Legal, professional, and practical aspects of psychotherapy education of psychiatrists in Germany

M. Linden

Department of Psychosomatic Medicine, Charité University Medicine Berlin, Berlin, Germany
doi: 10.1192/j.eurpsy.2025.168

Abstract: In Germany there are about 40.000 licensed psychological psychotherapists, 4.000 physicians who work as psychotherapists only, 8.000 psychiatrists who also are specialised in psychotherapy, 4.000 physicians specialised in psychosomatic medicine and psychotherapy, 1.000 physicians of child psychiatry, 35.000 somatic physicians with a training in psychosomatic basic care. This accounts for about 1 therapist for 1.000 inhabitants or 1 per 200 persons with mental problems in ambulatory care. All these therapists are fully reimbursed by health insurance. About 60% of all persons with mental problems have been treated in specialised outpatient psychotherapy.
There are furthermore 900.000 patients per year who are treated for 30 days on average in inpatient departments of psychiatry,

psychosomatic medicine and psychotherapy, and another 30.000 patients who are treated in about 300 psychosomatic rehabilitation hospitals for about four weeks.
Given these numbers and costs for psychotherapy, there are multiple regulations for the education and professional practice of therapists. Therapists must undergo three years of training either in cognitive behavior therapy or psychodynamic psychotherapy or systemic psychotherapy, while other forms of psychotherapy, such as Gestalt or Logotherapy are not allowed in training nor patient care. There are detailed requirements in regard to the number of theory lessons, therapeutic self-experience, and treatment with qualified supervision after four sessions. Psychotherapy practice is also restricted to these "scientifically accepted psychotherapies", which is overseen by two state committees. Depending on the psychotherapy school, health insurance reimburses up to 36 sessions for systemic psychotherapy, 80 for cognitive behavior therapy, 100 for psychodynamic psychotherapy and 300 for analytical psychotherapy.
In summary, psychotherapy in Germany is part of regular patient care and therefore submitted to all respective regulations.

Can network analysis inform diagnostic and treatment procedures? Evidence and perspectives in eating disorders

A. M. Monteleone

Department of Psychiatry, University of Campania L. Vanvitelli, Naples, Italy
doi: 10.1192/j.eurpsy.2025.169

Abstract: Introduction: The network theory of psychopathology has recently provided a novel view of mental disorders. A growing number of studies employing this methodology has been conducted in eating disorders (ED).
Objectives: Clinical implications of network approach to ED will be discussed spanning diagnosis and classification, comorbidity, prognosis, and treatment.
Methods: Evidence from literature studies and reviews exploring ED psychopathology and treatment through the use of network analysis will be provided. Limitations related to the employment of the network approach will be discussed along with recommendations for future directions.
Results: Overvaluation and concerns about body shape and weight and desire to lose weight are the most central symptoms across patients' ages and ED diagnoses. Internalizing symptoms, ineffectiveness, and low interoceptive ability play a central role in the psychopathology of ED and promote psychiatric comorbidity. The main issues of network analysis are the selection of network items and the use of cross-sectional data. Prognosis and mechanisms of treatment-induced changes are under-investigated areas.
Conclusions: Network analysis supports a description of ED psychopathology as including eating specific and general psychological symptoms. Treatments designed to improve the most central symptoms and their connections will be essential to explore assumptions of network theory. Longitudinal data from multilevel assessment will allow exploring within person trajectories of psychopathology, observing the dynamic nature of psychopathology and identifying risk and vulnerability factors. This approach will contribute to describe a staging model of EDs, that is essential to improve prognosis formulation and individualize treatment approaches.

Usefulness of severity criteria in DSM Eating Disorders and existing gaps

F. Fernandez-Aranda[1,*] on behalf of Eating Disorders Section, S. Jimenez-Murcia[1] on behalf of Eating Disorders Section and Eating Disorders Working Group

[1]Clinical Psychology, University Hospital of Bellvitge, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.170

Abstract: Anorexia nervosa (AN), bulimia nervosa (BN) and Binge Eating Disorders (BED) are diagnosed using the DSM-5 (American Psychiatric Association [APA] 2013) and its revised text (DSM-5-TR; APA 2022) or the ICD-11 (World Health Organization [WHO] 2019). While both systems use a severity indicator for AN based on body mass index (BMI), only the DSM-5 proposes a severity indicator for BN, based on the weekly frequency of purging behaviours, and, in the case of BED, based on the weekly frequency of binge episodes. These severity scores aim to index the level of general and eating disorder (ED) psychopathology, and thus, if valid, should serve as a crucial tool for tailoring treatment decisions, including duration, frequency and type of treatment. However, the current literature is contradictory with regard to the appropriateness of the criteria used and their validity. Therefore, alternative criteria have been proposed (e.g. drive for thinness, duration of the disorder…), especially when exploring chronicity and long-lasting EDs. Furthermore, few studies have directly examined the relationship between severity ratings and treatment outcome. In this presentation, we will discuss current gaps in severity indicators and potential alternatives. Data from existing longitudinal cohorts will be described.

What do we know about illness stages in anorexia nervosa?

U. Schmidt

Psychological Medicine, King's College London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.171

Abstract: Clinical stageing models are well-established in many areas of medicine, most notably in oncology. These models are used to determine personalised treatment options and indicate prognosis. In psychiatry, staging models have been developed most prominently for psychosis and mood disorders. These models are being used to guide treatment and service provision, e.g. through development of high-risk and early intervention services and stage-appropriate treatment delivery. Clinical staging models for obesity, incorporating medical history, clinical and functional assessments and routine diagnostic investigations also exist and appear to show improved clinical utility in assessing obesity- related risk and prioritising treatment. Recent generic frameworks for staging in mental health have highlighted that there is much individual variability in people's progression through different illness stages, and therefore there is a need to also specify stage modifiers (disease progression factors (e.g. cognitive or neural factors) and extension factors (e.g. physical complications)). Several staging models for eating disorders have been developed. Most of these focus on anorexia nervosa (AN). Criteria for stage differentiation are mostly based on combinations of cognitive, behavioural and physcial features, and illness duration. As yet most of these models are untested. In my talk I will summarise the available evidence on illness stages, stage modifiers and extension factors and their utility in AN and present evidence on what is known about stage-appropriate interventions. I will discuss implications for research and clinical practice.

ADHD and the Inflammatory Pathway: from infections to inflammations

I. Manor[1,2]

[1]ADHD clinic, Geha MHC, Petach-Tiqva and [2]psychiatric division, Faculty of Medicine and Health-ralted disorders, Tel Aviv University, Tel Aviv, Israel
doi: 10.1192/j.eurpsy.2025.172

Abstract: Attention-Deficit/Hyperactivity Disorder (ADHD) has been reported as a risk factor for COVID-19 infection and severity of illness. This presentation outlines the research trajectory that began during COVID-19 studies and has since demonstrated that ADHD is not only associated with an increased risk of infection but also with long-term COVID-19 syndrome (LCS). The chain of studies supporting these findings includes the association of ADHD with infections and inflammatory/autoimmune disorders, such as Glucose-6-Phosphate Dehydrogenase (G6PD) deficiency and Familial Mediterranean Fever (FMF). These links, alongside globally reported associations between ADHD and other autoimmune disorders, such as Systemic Lupus Erythematosus (SLE), underscore the potential involvement of inflammatory and immune dysregulation in the pathophysiology of ADHD. The emerging data linking ADHD with inflammatory conditions—at both clinical and genetic levels—represents a significant new direction in ADHD research. Further investigation into these connections may provide deeper insights into the underlying mechanisms of ADHD and contribute to developing novel therapeutic strategies.

Immune mechanisms and medical comorbidity in ADHD: a narrative review

J. H. Newcorn

Psychiatry, Icahn School of Medicine at Mount Sinai, New York, United States
doi: 10.1192/j.eurpsy.2025.173

Abstract: Introduction: The potential role of inflammatory and immune pathways in ADHD pathophysiology and pathogenesis has received considerable recent attention. Some of these pathways are long-studied in ADHD because of known or suspected mechanisms of high frequency comorbidities, such as obesity, sleep disorders, cardiovascular system disorders/migraine, atopic illnesses, and several autoimmune diseases. Aberrant cellular functioning, aberrant glial functioning, and/or aberrant mitochondrial dysfunction have all been implicated in mechanistic studies. While we separate these mechanisms conceptually, in reality they are intertwined and communicate with each other in a multi-directional complex of mechanisms.
Objectives: To introduce the relationships among inflammation, immune mechanisms and ADHD, and provide a high level overview of current and cutting edge research in this area. We will review data linking ADHD with inflammation and immunologic mechanisms, recent findings on the genetic underpinnings of medical comorbidity in ADHD, and the relationship between maternal inflammation and genetic risk for ADHD in offspring.
Methods: This is a focused, narrative review of recent literature in the field.
Results: Epidemiological, genetic, and biomarker data converge to illuminate the pleiotropic role of immune mechanisms in the pathophysiology of ADHD. Suspected mechanisms include both innate and adaptive pathways. Epigenetic vulnerabilities interact with environmental factors to confer greater risk for health problems among individuals with ADHD. Likewise, many of these same risk factors also carry increased risk for ADHD.
Conclusion: This information exemplifies the close relationship between psychiatric and medical conditions and/or their risk factors. The high heritability of the immune system and associated immunological dysfunctions provides a novel approach to understand the mechanisms through which gene-environment interactions may contribute to the occurrence and clinical presentation of ADHD.

Typical clinical manifestations of anxiety and depression in patients with medical illness and general notions about their treatment

L. Bartova

Department of Psychiatry and Psychotherapy, Clinical Devision of General Psychiatry, Medical University of Vienna, Vienna, Austria
doi: 10.1192/j.eurpsy.2025.174

Abstract: Anxiety and depression are common psychiatric comorbidities in chronic medical illnesses, such as cardiovascular, endocrine, and neurological diseases. These conditions are associated with greater disease severity, poorer functional outcomes, and reduced quality of life for patients and their families. Despite their significant global burden, they are often underdiagnosed due to overlapping symptoms with primary medical conditions. Symptoms in medically ill patients may differ from classic psychiatric presentations, often involving heterogeneous (psycho)somatic phenomena like fatigue, autonomic irregularities, gastrointestinal symptoms, sleep disturbances, and cognitive impairments. Anxiety typically manifests as hypervigilance, excessive worry, and irritability, while depression presents with persistent sadness, psychomotor slowing, and loss of motivation, pleasure, and interest. Subsyndromal symptoms, though often untreated, can exacerbate functional decline and disease progression. Effective management requires a multimodal approach, with modern psychopharmacotherapy as a cornerstone. Selective Serotonin Reuptake Inhibitors (SSRIs) and Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs) are recommended first-line treatments due to their safety and efficacy. In case of insufficient response, add-on strategies may include second-generation antipsychotics, lithium, esketamine, or pregabalin for predominant anxiety. Emerging evidence supports the use of phytotherapeutics as Silexan and Rhodiola rosea for subsyndromal symptoms. Non-pharmacological interventions also play an important role. Cognitive Behavioral Therapy remains the first-line psychotherapeutic option, complemented by mindfulness techniques, psychoeducation, biofeedback, and relaxation strategies, particularly for anxiety. Chronobiological treatments like bright-light therapy and sleep deprivation have proven effective for depression, especially in seasonal patterns. Brain stimulation methods, including transcranial magnetic stimulation and electroconvulsive therapy, may also be considered based on individual needs. Importantly, successful physician-patient interactions, directly and promptly addressing emotional and psychological concerns during consultations and daily rounds, are crucial in fostering treatment adherence and improving outcomes. In conclusion, anxiety and depression in medically ill patients present unique diagnostic and therapeutic challenges. Early recognition and individualized, multimodal treatment strategies can enhance adherence and outcomes. Integrating pharmacological and non-pharmacological approaches within collaborative care models and recommended treatment algorithms is essential for effectively addressing individual clinical presentations.

Psychopharmacological treatment of anxiety and depression in patients with diabetes. Pharmacodynamics and pharmacokinetic considerations, drug interactions

F. Novais[1]* and D. Telles-Correia

Faculdade de Medicina, Lisboa, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.175

Abstract: Anxiety and depression are prevalent mental health conditions in patients with diabetes, significantly impacting their quality of life and complicating glycaemic control. The interplay between psychopharmacological agents and diabetes medications presents unique challenges in managing both mental health and metabolic conditions. This presentation reviews of psychotropic drugs commonly used to treat anxiety and depression in diabetic patients, with a focus on their efficacy, safety, and potential adverse effects. Special attention will be given to drug interactions between antidepressants, anxiolytics, and antidiabetic medications, which can influence treatment outcomes. Key considerations include the effects of psychotropic agents on insulin sensitivity, glucose metabolism, and the risk of hypoglycaemia. The presentation will also discuss personalized treatment strategies, adjusting for individual patient profiles and comorbidities. By integrating both psychiatric and endocrinological perspectives, we aim to improve clinical outcomes through optimized pharmacological management and minimize the risk of adverse drug interactions in this vulnerable patient population.

Psychopharmacological treatment of anxiety and depression in patients with liver and/or kidney disease. Pharmacodynamics and pharmacokinetic considerations, drug interactions.

M. Stuhec[1,2]

[1]Pharmacology Department, Medical Faculty Maribor, University of Maribor, Maribor and [2]Clinical Pharmacy, Ormoz Psychiatric Hospital, Ormoz, Slovenia
doi: 10.1192/j.eurpsy.2025.176

Abstract: Psychopharmacological treatment of anxiety and depression in patients with liver and/or kidney disease is complex, primarily due to the differences in pharmacokinetics compared to healthy individuals. Most medications are excreted via the kidney and/or liver, so dose adjustments are often necessary in these patients. Drug-drug interactions are also a significant clinical concern in liver and/or kidney disease, making regular monitoring essential. These factors may contribute to treatment relapse and severe adverse drug reactions associated with psychotropic medications and comedications. Medication selection is, therefore, based on these considerations. Clinicians must regularly monitor kidney and liver function,

although there are no clear global recommendations. A summary of product characteristics is the primary guideline for dose adjustments related to kidney and liver function, though it has limitations and is updated slowly. The most important monitoring parameters for these patients are liver enzymes and serum creatinine levels.
Patients with liver and/or kidney disease are often excluded from randomized controlled trials, meta-analyses, and clinical guidelines, resulting in a lack of data specific to this population. This issue is even more relevant in elderly patients treated with polypharmacy, as many somatic medications can worsen liver and/or kidney function in patients with anxiety and depression. In this context, some medications, such as vortioxetine, trazodone, agomelatine, quetiapine, and sertraline, are less affected by kidney disease in terms of pharmacokinetics.
Several tools are available for prudent medication selection and monitoring in these patients, including medication lists (e.g., Beers, Priscus), therapeutic drug monitoring (TDM), and collaboration with clinical pharmacists and/or pharmacologists. In this presentation, the presenter will discuss this topic from both pharmacological and clinical perspectives. Participants will learn the fundamental pharmacokinetic aspects necessary for medication selection in these patients, which are valuable for daily practice.

Basic symptoms in the community: prevalence, clinical significance and course

C. Michel[1*] and F. Schultze-Lutter[2]
[1]University Hospital of Child and Adolescent Psychiatry and Psychotherapy, University of Bern, Bern, Switzerland and [2]Department of Psychiatry and Psychotherapy, Medical Faculty, Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.178

Abstract: Objectives: The subtle, subjective nature of basic symptoms (BS) has often led to doubt regarding their clinical significance. **Methods:** We therefore examined the prevalence, clinical significance and course of BS over three years in a large sample (N = 2684) of 16- to 40-year-old residents of the Swiss canton of Bern (response rate: 64%). At follow-up, persons with a lifetime risk symptom at baseline were compared with control subjects (N = 834; response rate 66%). Fourteen criteria-relevant BSs were assessed by trained clinical psychologists over the telephone, along with information on symptomatic ultra-high-risk symptoms, mental disorders and functioning.
Results: At baseline, 18% of the participants reported any lifetime BS, 10% had still experienced one in the three months prior to the interview. In general, BS were rare, and only 2% of the participants met any BS criteria, which was significantly associated with non-psychotic mental disorders (OR = 5) and especially with functional deficits (OR = 16). At follow-up, five individuals had developed psychosis, one with BS criteria and three more with BS at baseline. In addition, 95% of the participants no longer met the BS criteria, while 3% reported new BS criteria.
Conclusions: Although BS are not rare phenomena in the community, they rarely persist and rarely occur frequently enough to meet the requirements of the risk criteria. Furthermore, they do not appear to occur randomly, but are restricted to a subpopulation of vulnerable individuals – possibly occurring in times of stress and/or low mood and functional difficulties in these individuals.

Basic symptoms – lessons from Spanish-speaking countries

N. Jimeno[1,2]
[1]Psychiatry, University of Valladolid and [2]Research Group on Clinical Neuroscience of Castile and Leon, Valladolid, Spain
doi: 10.1192/j.eurpsy.2025.179

Abstract: The main contributions of Spanish and Hispano-American authors to the study of basic symptoms, either published in Spanish and English, will be briefly presented. Former publications mainly included translation and validation of different versions of the Frankfurt Complaint Questionnaire, transversal and longitudinal studies, and their role for psychosocial rehabilitation, also in a Penitentiary Psychiatric Hospital. More recent research includes the network analysis of basic, attenuated, and frank psychotic symptoms on 460 subjects attending a German early detection service, where disorganized communication, delusions and hallucinations were the most

central symptoms. Interestingly, cognitive and perceptual disturbances, included in basic symptom criteria, appeared to develop across attenuated symptoms to frank positive psychotic symptoms. Concerning the finding of three clusters of symptoms, "subjective disturbances", "positive symptoms and behaviors", and "negative and anxious-depressive symptoms", the predominately attenuated hallucinations of both SIPS and PANSS joined the basic symptoms in "subjective disturbances", therefore underlining the importance of insight in separating true psychotic hallucinations from other hallucinatory experiences and not justifying antipsychotic medication.

The phenomenology of dysphoric mood: exploring the lived experience

O. Doerr-Zegers[1]* and H. Pelegrina Cetran[2]

[1]Facultad de Medicina Universidad de Chile, Hospital-Instituto Psiquiátrico, Santiago, Chile and [2]Universidad Católica Argentina, Mendoza, Argentina
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.180

Abstract: Dysphoria is a complex phenomenon, which must be defined in the framework of different forms of affections. It belongs to the broader field of emotions, which are characterized by some essential features: i.e. movement, passiveness, transitoriness, and reference to the others. All these four essential features of emotion are specifically altered in depression. In discussing dysphoria, a first distinction is made between particular and global affections. The first type encompasses emotions and feelings, while the second one includes humor, mood and temper. Dysphoria belongs to one of these global affective states: the humor, which has to do with the spatial dimension of existence. In dysphoria, the patient experiences the world as oppressive and invasive of his/her intimacy; the others are lived as persons demanding answers or actions he/she is not able to fulfill. Finally, the phenomenology of dysphoria is analyzed through the four essential features described above and examples are given. Irritability – as Kraepelin taught us more than 100 years ago- is the most frequent psychic condition of these patients. The humor is very instable and depending, above all, on the interpersonal relationships. It is a typical humor of premenstrual disorder, but also of the borderline personalities, as Stanghellini and Rosfort (2013) have so clearly showed. We have also observed dysphoria in two other conditions, depression and mania, though with different nuances in the form of presentation. Finally, we would like to show how the different features characterizing emotion in general, which are derived from the etymology of the word, are present in dysphoria. First, the movement appears in dysphoria as a corporal restlessness always accompanying irritability. The dysphoric state is the opposite of being in peace with oneself and with the world. It is being under pressure, urgency, loss of control, impulsivity. Second, passivity: the subject cannot decide to be in one state or the other: dysphoria happens without notice and invades the subject, who is unable to defend himself against it. Borderline patients are unable to take distance from their emotional states and particularly from dysphoria, blaming others for the consequent discomfort. The third element is transitoriness. This feature is particularly observed in premenstrual disorder. Menstruation begins and the state disappears. Something similar occurs with pre-depressive dysphoria. In manias, by contrast, dysphoria only diminishes with the treatment. The last element we infer from the etymology of emotion is commotion, that is, its permanent reference to the other. The active participation of the other in the dynamic of dysphoria is particularly evident in borderline personalities, but also in depressive and manic dysphoria, but not in premenstrual syndrome.

Decoding dysphoria and violence: phenomenological insights to diagnosis and therapeutic interventions

L. Madeira

Universidade de Lisboa, Faculdade de Medicina, Lisboa, Portugal
doi: 10.1192/j.eurpsy.2025.181

Abstract: Aggressive emotions—such as anger, rage, envy, and resentment—play a complex role in human experience, spanning personal, social, and psychopathological dimensions. While anger can serve as a protective, communicative, or motivational force, it can also escalate into destructive emotions such as revenge, hatred, or resentment. This talk explores the phenomenology, psychology, and psychopathology of aggressive emotions, drawing from philosophical, psychoanalytic, and neuroscientific perspectives. These have a bodily-affective nature, shaping perception, behavior, and interpersonal dynamics (Schmitz, 2019; Landweer, 2020). While anger is often a reaction to a perceived transgression, it also functions as a regulatory mechanism for social norms and personal boundaries (Berkowitz, 1962; Bandura, 1973). I examine the ontological independence of emotions, showing how their spatial and embodied qualities influence their regulation and transformation (Fuchs, 2005). A key focus will be the transformation of anger into resentment and revenge, using Nietzsche and Scheler's theories of ressentiment to explore how powerlessness fuels hostility (Nietzsche, 1887; Scheler, 1912). We discuss how pathological resentment differs from normative anger, leading to chronic hostility, ideological fixation, and moral superiority complexes. Finally, I analyze the role of aggressive emotions in psychopathology, considering their manifestations in personality disorders, trauma-related disorders, and psychotic states (Novaco, 1979; Cameron, 1943). From paranoia's persecutory anger to the dysregulated aggression of borderline and antisocial personalities, the keynote explores how anger-related emotions are structured, experienced, and acted upon across clinical categories.

Phenomenology of Gender Dysphoria

C. Alves[1]* and B. Ferreira

Hospital Júlio de Matos, Lisbon, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.182

Abstract: Introduction: Gender dysphoria (GD) is defined by the presence of clinically significant suffering associated to the marked incongruence between the experienced gender and the one which was assigned at birth. The inherent duplicity to the human condition forces us to reflect on the fact that, in some cases, the body may be the most intimate piece of the Self, whilst also being the most foreign one. The experience of feelings of shame and hatred for oneself and the importance of the Other's gaze are pressing in GD, which presents as deeply impactful in the individual's functioning.
Objectives: This review aims to identify and explore the phenomenology of the suffering so often mentioned by GD patients, but which has been ignored and remains mainly unidentified in the psychopathology realm.
Methods: Through the exploration of both the PubMed database and publications by philosophers who have been, throughout the years, approaching the gender theme and distinguishing its evolution along the years, I aim to review the qualitative literature available of the dissection of the different domains of GD.
Conclusions: GD is an ever growing psychiatric diagnostic, frequently presenting with psychiatric comorbidities. Its treatment poses as highly effective, while its consequences may be pervasive and affecting different domains of the individual's functioning. The exploration of gender identity may be a never ending journey, which makes the acknowledgement of the associated psychopathology fundamental in the design of a truly empathic relationship with these patients.

Impulsiveness and dysphoria as pharmacological targets: Can we aim at a phenomenologically informed therapeutic intervention?

S. Jerotic[1,2]

[1]Faculty of Medicine, University of Belgrade and [2]Clinic for Psychiatry, University Clinical Centre of Serbia, Belgrade, Serbia
doi: 10.1192/j.eurpsy.2025.183

Abstract: Dysphoria and impulsivity are embodied experiences that pervade numerous psychiatric conditions and evade easy categorization within traditional diagnostic boundaries. Phenomenological approaches are needed in order to clarify underlying experiential structures. Psychopharmacology has traditionally been perceived as a "biological intervention", where success is measured by its impact on symptom clusters outlined in the ICD and DSM frameworks, ignoring the specific impact of medication on lived bodies and existential states. An embodied approach to psychopharmacology integrates phenomenology, neuroscience, and physiology, moving beyond traditional reductive perspectives. By examining how medications influence not only symptoms but also the lived experience and embodied sense of self, we can develop a more nuanced understanding of their effects, and possibly strive towards development of distinct phenomenological profiles of medication, which would enhance our understanding of dysphoria and impulsivity.

Physical health in subjects with Schizophrenia: where are we?

A. Mucci

Mental and Physical Health and Preventive Medicine, University of Campania L. Vanvitelli, Naples, Italy
doi: 10.1192/j.eurpsy.2025.184

Abstract: People living with schizophrenia (PLWS) face one of the most significant health equality gaps in Europe. Their life expectancy is 15–20 years shorter than that of the general population, mainly because they are affected at an earlier age by preventable physical illnesses, but encounter barriers in accessing adequate care. PLWS did not benefit from prevention campaigns for cardiovascular, oncologic, or metabolic risk. Antipsychotics might add to the cardiometabolic risk and represent a further reason for monitoring and treating emergent conditions. Notwithstanding international guidance papers or national guidelines, PLWS do not receive adequate screening and treatment. This presentation will summarize national and international efforts to reduce this health equality gap, illustrating the minimum screening procedures and several interventions that can be integrated into schizophrenia treatment to improve health outcomes of PLWS.

The association between glucose 6-phosphate dehydrogenase (G6PD) deficiency and attention deficit/hyperactivity disorder (ADHD)

B. Krone

Psychiatry, Icahn School of Medicine at Mount Sinai, NYNY, United States
doi: 10.1192/j.eurpsy.2025.185

Abstract: Introduction: Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked genetic enzymopathy that impacts 4.9% of the population, with greater prevalence among Mediterranean, East Asian, and African populations. G6PD deficiency results in levels of nicotinamide-adenine dinucleotide phosphate (NADPH) and glutathione (GSH) that are insufficient for maintaining the balance of oxidation-reduction in the body. This results in elevated production of reactive oxygen species (ROS), oxidative stress on proteins and lipids, damage to DNA, and potential activation of chemokine and cytokine pathways by astrocytes and microglia. We propose that these direct and indirect effects of G6PD deficiency are associated with development of ADHD.
Objectives: This study investigated the association between G6PD deficiency and Attention Deficit/Hyperactivity Disorder (ADHD).

Methods: The study involved 7,473 G6PD-deficient patients and 29,892 matched case-controls (selected at a 1:4 ratio) from a cohort of 1,031,354 within the Leumit Health Services database. Clinical characteristics were analyzed using Fisher's Exact Tests for categorical variables and Mann-Whitney U tests for continuous variables.
Results: The average age of patients was 29.2 ± 22.3 years, with 68.7% being male. The mean follow-up duration was 14.3 ± 6.2 years. Individuals with G6PD deficiency showed a significant 16% higher risk of being diagnosed with ADHD (Odds Ratio (OR) = 1.16 [95% CI, 1.08-1.25], $p < 0.001$) on follow up. Furthermore, G6PD deficiency was associated with a 30% greater likelihood of seeking care from adult neurologists (OR = 1.30 [95% CI, 1.22-1.38], $p < 0.001$) and a 12% higher probability of consulting adult psychiatrists (OR = 1.12 [95% CI, 1.01-1.24], $p = 0.048$). The use of stimulant medications among G6PD deficient individuals was 17% higher for methylphenidate class drugs (OR = 1.17 [95% CI, 1.08, 1.27], $p < 0.001$), and use of amphetamines elevated by 16% (OR = 1.16 [95% CI, 1.03, 1.37], $p = 0.047$).
Conclusion: This study establishes a significant association between G6PD deficiency and an increased risk of ADHD diagnoses. These findings suggest potential opportunities for the development of culturally sensitive interventions.

Hypermobility, immune dysfunction and dysautonomia cluster in ADHD

J. Kustow

Director of Education, UK Adult ADHD Network, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.189

Abstract: Emerging research reveals a striking overlap between ADHD, hypermobility syndromes, immune dysfunction, and autonomic dysregulation. Studies suggest that approximately half of individuals with ADHD are hypermobile, while ADHD is significantly over-represented in those with hypermobility syndromes, such as Hypermobile Ehlers-Danlos Syndrome (hEDS) and Hypermobility Spectrum Disorder (HSD). Unlike benign joint hypermobility, these syndromes involve multisystem pathology, often accompanied by dysautonomia (e.g., postural orthostatic tachycardia syndrome, POTS), mast cell activation disease (MCAD), and autoimmune conditions.
This 'somatic super-syndrome' encompasses many of ADHD's under-recognised somatic comorbidities, including hypermobility, allergy and autoimmunity, POTS, fatigue and pain syndromes (Chronic Fatigue Syndrome and Fibromyalgia Syndrome), and sensory processing issues, amongst others. A small but growing body of evidence suggests that mast cells - 'first responder' immune cells involved in allergic and inflammatory responses - play a critical role in neurocognitive function and that their excessive activation has been associated with a range of neurological and psychiatric/neurodevelopmental conditions. Could a similar issue with aberrant mast cell activation be contributing to the pathophysiology of ADHD.
Dr. James Kustow, consultant psychiatrist and adult ADHD specialist, will present the latest insights into this complex interplay between connective tissue dysfunction, chronic low-level inflammation, and autonomic dysregulation. He will explore how these factors may, in some, drive an ADHD-like syndrome and discuss emerging research on neuroimmune mechanisms linking ADHD with inflammatory disorders such as infections, asthma, rhinitis, and food allergies.
By illuminating these connections and reviewing the available evidence, this presentation will encourage a broader, integrative approach to understanding and managing ADHD. It will also consider how future research might inform novel therapeutic strategies targeting immune dysregulation and autonomic dysfunction in ADHD.

Disclosure of Interest: J. Kustow Consultant of: I have done some consultancy work for a couple of pharmaceutical companies but not for over 3 years, Speakers bureau of: I have previously spoken at and chaired events organised by pharmaceutical companies (but I dont speak on the subject of ADHD medication).

Artificial Intelligence-based Psychotherapy Practices

F. H. Kraxner and EPA Section of Psychotherapy

Center of Psychiatry and Psychotherapy, Hospital of Affoltern, Zurich, Affoltern, Switzerland
doi: 10.1192/j.eurpsy.2025.220

Abstract: Artificial Intelligence (AI) is revolutionizing the field of psychotherapy by introducing innovative, accessible, and efficient methods for mental health care. AI-based psychotherapy practices leverage machine learning algorithms, natural language processing (NLP), and predictive analytics to provide personalized therapeutic interventions, support mental health practitioners, and enhance patient outcomes. These systems, including virtual therapists and chatbot platforms, are designed to simulate human empathy, analyze user inputs, and deliver evidence-based therapeutic techniques such as cognitive-behavioral therapy (CBT).
Moreover, AI systems assist clinicians by offering diagnostic support, monitoring patient progress through behavioral data analysis, and optimizing treatment plans. The integration of AI into psychotherapy practices has shown promise in addressing barriers such as stigma, geographic limitations, and therapist shortages. However, ethical challenges related to data privacy, algorithmic bias, and the therapeutic efficacy of AI-driven interactions remain significant concerns. This abstract explores the potential, applications, and limitations of AI-based psychotherapy, emphasizing the need for rigorous research and ethical considerations to ensure its effective and responsible integration into mental health care.

CBS002

Artificial intelligence and psychotherapy interventions

R. Karaliuniene

Clinic for Psychiatry and Psychotherapy, Rhein Mosel Clinic, Andernach, Germany
doi: 10.1192/j.eurpsy.2025.221

Abstract: This presentation explores the intersection of psychotherapy interventions and AI, focusing on how AI can be leveraged to augment traditional therapeutic methods. AI-powered tools such as chatbots, virtual therapists, and predictive analytics will be covered. Additionally, the talk will address the ethical implications, challenges, and opportunities posed by the use of AI in mental health care, emphasizing the importance of maintaining the human element in therapy. Drawing on current research and case studies, possible opportunities of AI assisted therapists in identifying patterns in patient behavior, improving treatment efficacy, and reducing barriers to mental health care, especially in underserved populations will be explored. The presentation will conclude with a forward-looking perspective on how AI and psychotherapy can collaboratively evolve to shape the future of mental health care.
Keywords: Artificial Intelligence, Psychotherapy, Mental Health, Chatbots, Virtual Therapy, Ethical Considerations, Personalized Treatment.

CBS003

Limitations of Artificial Intelligence-Based Tools in Psychotherapy

B. Ozel

Department of Psychiatry, Mus State Hospital, Mus, Türkiye
doi: 10.1192/j.eurpsy.2025.222

Abstract: Artificial intelligence (AI) tools have gained attention for their potential to transform mental health care. However, in the context of psychotherapy, these tools reveal fundamental limitations that warrant critical analysis.

Psychotherapy is deeply rooted in relational dynamics, cultural sensitivity, and the ability to engage with the complex emotional landscapes of individuals. Current AI-based tools often struggle to address these dimensions adequately. While language models can generate coherent and seemingly empathetic responses, their inability to genuinely understand and respond to nuanced human emotions and interpersonal subtleties presents a significant barrier (Floridi & Chiriatti, 2020).

Ethical concerns also pose considerable challenges. The use of AI in psychotherapy raises questions about data privacy, algorithmic transparency, and the potential perpetuation of biases within AI systems. Such issues not only risk undermining the therapeutic process but may also erode trust in these technologies.

The therapeutic alliance—a critical factor in psychotherapy—represents another area of concern. Effective therapy relies heavily on building trust, mutual understanding, and a genuine connection, all of which are difficult to replicate with AI-based tools. Current research suggests that while AI can support certain therapeutic tasks, its capacity to maintain and enhance the therapeutic alliance remains unproven (Linardon et al., 2019).

This presentation will critically examine these limitations through case-based discussions and clinical reflections. By highlighting the inherent challenges of integrating AI into psychotherapy, it aims to encourage thoughtful and cautious exploration of its applications, emphasizing the importance of preserving the relational and ethical foundations of psychotherapeutic practice.

How to start medication for ADHD?

O. Kilic

Department of Neurosciences, Bezmialem Vakif University, Institute of Health Sciences, Istanbul, Türkiye
doi: 10.1192/j.eurpsy.2025.223

Abstract: Starting medication for attention deficit and hyperactivity disorder (ADHD) in adults begins with a thorough evaluation. Diagnostic evaluation should involve a careful investigation of the psychiatric and medical comorbidities and an interview with the patient and family members or partners. The next step is to assess the severity of ADHD symptoms, comorbidities and their impact on functioning. This will help guide the order in which targeted treatments are introduced. When selecting the medication, considerations such as the presentation of ADHD symptoms, the patient's medical history, previous responses to ADHD treatments, and preferences about the effect onset are crucial. This choice typically lies between stimulant and non-stimulant options. The initial dose prescribed should be low enough to mitigate potential side effects while still effectively alleviating symptoms and gradually improving functioning. Treating comorbid psychiatric disorders, such as depression, anxiety, and substance use disorders, is equally important alongside ADHD treatment. The dosage should be slowly adjusted based on the patient's response and any side effects that arise. Regular follow-up appointments are essential during this phase to monitor the medication's effectiveness, identify side effects, and make necessary dosage adjustments. Dr Ozge Kilic will discuss key tips related to assessment, medication selection, titration, adjusting dosages, and managing side effects through clinical case vignettes.

Female-specific pharmacotherapy in ADHD: premenstrual adjustment of psychostimulant dosage

M. De Jong[1,2,3*] and D. S. Wynchank[1]

[1]Expertise Centre Adult ADHD, PsyQ, The Hague; [2]VU Medical Centre, Amsterdam Public Health Research Institute and [3]Department of Psychiatry, Amsterdam UMC/VUmc, Amsterdam, Netherlands

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.224

Abstract: Objective: Attention-Deficit/Hyperactivity Disorder (ADHD) is a common neurodevelopmental condition which is underdiagnosed and undertreated in women. For decades, the ADHD field has called for more insight into female-specific therapy. Preliminary findings postulate that changes in sex hormones during the menstrual cycle may influence the effectiveness of psychostimulant medication. Yet, pharmacotherapeutic interventions tailored to women with ADHD remain scarce. Previously, our group showed an increase in mood symptoms in the premenstrual week in women with ADHD. Premenstrual worsening of depressive and ADHD symptoms represent a treatment challenge.

In our adult ADHD clinic, we noted several women describing exacerbation of their ADHD and depressive symptoms in the premenstrual week and/or insufficient effect of their established dosage of psychostimulant. We responded to the need expressed by these women by increasing their stimulant dosage in the premenstrual week, while monitoring the response and side effects.

Methods: This community case study of nine consecutive women being treated for ADHD and co-occurring conditions (including depression and premenstrual dysphoric disorder), reports our local experience of increasing the individually prescribed psychostimulant dosage during the premenstrual period. We methodically monitored the effect of this increased dosage on ADHD symptoms, mood and somatic symptoms for the following 6-24 months.

Results: With premenstrual dose elevation, all nine women experienced improved ADHD and mood symptoms with minimal adverse events. Premenstrual inattention, irritability and energy levels improved, and now resembled the other non-premenstrual

weeks more closely. All women decided to continue with the elevated premenstrual pharmacotherapy.
Discussion: Our preliminary results demonstrate potential benefits of increasing premenstrual psychostimulant dosage in women with ADHD, experiencing premenstrual worsening of ADHD and mood symptoms. The results concur with previous findings of diminished response to amphetamines in the late luteal phase. Increased dosage may help combat premenstrual worsening of cognitive and emotional symptoms in women with ADHD, with significant clinical implications. Better management of premenstrual ADHD and mood symptoms in vulnerable women can improve treatment outcome and meet an unmet need. However, implementation should be individually explored. Further investigation of luteal phase psychostimulant dose adjustment is required for safe, optimal and individualised treatment for women with ADHD. Specifically, we are currently applying for funding to set up the ADAPT-trial (Adjusting Premenstrual Psychostimulant Dosage for Women with ADHD: Enhancing Efficacy).

CBS006

How to manage non-response using stimulants?

A. Philipsen

Privatpsykiaterne, Sorø, Denmark
doi: 10.1192/j.eurpsy.2025.225

Abstract: Introduction/background: Psychiatrist working with ADHD-patients since 2007.
Method: I have diagnosed and treated more than a 1000 patients with ADHD. I have always, when it has been possible, given one medication at a time to be able to evaluate how it works, and what gives side effects.
Results: When stimulants suddenly don't work anymore, I have searched for physical and psychological problems that could explain it. By solving these problems, the stimulants work again.
Conclusion: By working this way, we have noticed that patients have a high compliance, and there are a lot less cases of relapse with ADHD symptoms.

CBS007

Therapeutic drug monitoring for mood stabilizers in elderly: a case report

G. Schoretsanitis

Department of Psychiatry, Psychotherapy and Psychosomatics, Hospital of Psychiatry, Zurich, Switzerland
doi: 10.1192/j.eurpsy.2025.226

Abstract: The management of elderly patients receiving polypharmacy presents significant clinical challenges due to age-related physiological changes, the prevalence of chronic conditions, and the potential for drug-drug interactions and adverse drug reactions (ADRs). Blood level assessments of medications provide a critical tool for optimizing pharmacotherapy in this population. Here we present the benefits of therapeutic drug monitoring (TDM) and pharmacokinetic assessments in the personalized management of elderly patients with polypharmacy. Regular monitoring of blood drug concentrations can identify drug-drug interactions, related toxicity risks, and adherence issues, thereby informing dosage adjustments to achieve optimal therapeutic outcomes.

Disclosure of Interest: G. Schoretsanitis Consultant of: Dexcel, Saladax, HLS Therapeutics, Speakers bureau of: Saladax, HLS Therapeutics, Lundbeck, Thermo Fisher.

CBS008

Pharmacokinetic background of therapeutic drug monitoring in this case

M. Stuhec[1,2]

[1]Pharmacology Department, Medical Faculty Maribor, University of Maribor, Maribor and [2]Clinical Pharmacy, Ormoz Psychiatric Hospital, Ormoz, Slovenia
doi: 10.1192/j.eurpsy.2025.227

Abstract: The pharmacological effect is the result of both pharmacokinetic (e.g., how the body affects the medication) and pharmacodynamic (e.g., how the medication affects the body) processes occurring simultaneously. Pharmacokinetics includes the processes of liberation, absorption, distribution, metabolism, and elimination (LADME). These processes govern the steady-state plasma concentration (Css). Therapeutic drug monitoring (TDM) is a pharmacological tool used to select and adjust medications. TDM enables Css measurements and dose adjustment calculations. In this presentation, the presenter will cover the main pharmacokinetic issues related to TDM in this clinical case, including Css determination, therapeutic range, dose adjustment, and pharmacokinetic calculations. Participants will learn the fundamental pharmacokinetic aspects necessary for understanding the case.

CBS009

Therapeutic drug monitoring in clozapine treatment

P. Mohr[1,2]

[1]National Institute of Mental Health - CZ, Klecany and [2]3rd Faculty of Medicine, Charles University, Prague, Czech Republic
doi: 10.1192/j.eurpsy.2025.228

Abstract: Although still somewhat reluctantly used (and thus underutilized) by many clinicians, it is the well-evidenced fact that clozapine is an effective drug for treatment-resistant schizophrenia. In order to optimize its therapeutic potential and to minimize side effects, therapeutic drug monitoring (TDM) of plasma clozapine and N-desmethylclozapine is an essential clinical tool. TDM can also help to reveal insufficient adherence or individual differences in the rates of metabolism. Moreover, clozapine plasma levels can

be affected by other factor, such as smoking or concomitant medication (fluvoxamine). In our study sample, we were able to demonstrate the relationship between the dosage and clozapine plasma levels and their impact on clinical efficacy and safety.

How to Use Therapeutic Drug Monitoring for Comorbidities Management in This Case

J. Benninghoff

Zentrum für Altersmedizin und Entwicklungsstörungen - ZfAE, kbo, München, Germany
doi: 10.1192/j.eurpsy.2025.229

Abstract: Therapeutic Drug Monitoring (TDM) plays a crucial role in optimizing treatment for patients with psychiatric disorders and comorbid medical conditions, particularly in the elderly. This talk will focus on the practical application of TDM in managing polypharmacy and drug-drug interactions in a geriatric patient with mood disorders. Using a case-based approach, the discussion will highlight how TDM can guide dose adjustments, improve treatment efficacy, and minimize adverse effects in patients with multiple comorbidities.
Emphasizing real-world clinical challenges, this session will provide practical insights into integrating TDM into psychiatric practice, ensuring safer and more effective pharmacotherapy. Audience interaction will be encouraged through live voting and discussion to enhance learning and application in daily clinical settings.

Mosè Barabba: A case study between forensic and cultural psychiatry

J. Santambrogio*, Antonino Giancontieri, Elisabetta Leon, Elena Miragliotta, Enrico Capuzzi, Fabrizia Colmegna and Massimo Clerici

Disability Unit, ASST Brianza, Limbiate, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.230

Abstract: The presentation gives a narrative account of a case of ethnopsychiatry and criminology from the standpoint of the care network, with personal details supplied by the patient himself. The person involved, Mosè Barabba, was born in Sierra Leone where he was kidnapped and forced to become a child soldier at a very early age. He was brainwashed, brutalized and taught to admire and practice violence. He arrived in Italy at 16 years of age after a traumatic journey through North Africa, homeless and alone. At 19 years old, he was hospitalized for drug abuse, and then cared for by various associations (NAGA, CPS, SPDC). The presentation outlines his descent into substance abuse-induced violence and the first encounter with the law when he was twenty-five years old, followed by a return to a criminal environment after a first experience in a community. He was diagnosed with PSTD, NOS psychosis, behavioral issues related to substance abuse and chronic multifactorial hepatopathy. By the time he was 28 his violence had spiraled out of control and he was hospitalized by TSO, where the violence continued. He was committed to a two-year period in a REMS 1 , for psychopharmacological therapy with mood stabilizers. On his release from the REMS, he was placed in a rehabilitation program in AS.FRA 2 where positive results were obtained: his pathology was stabilized, with support he was able to abstain from substances and alcohol and he was receptive to therapy and rehabilitation. In 2021, then 31 years old, Mosé was considered to be well integrated into the community and was transferred to a CPA (a high protection residence for patients with psychiatric diagnosis).

CBS012

Crime: between symptom and trauma

F. Boaron

Dipartimento ad attività integrata Salute Mentale e Dipendenze Patologiche, AUSL Reggio Emilia, Reggio Emilia, Italy
doi: 10.1192/j.eurpsy.2025.231

Abstract: Exposure to Adverse Childhood Experiences (ACEs) represents a significant, dose-dependent risk factor for the development of numerous psychiatric and physical disorders (including diabetes, myocardial infarction, obesity, alcoholism, drug addiction, etc.), as well as for poorer social outcomes (dropping out of school, unemployment, economic decline, unwanted pregnancies) and violent behaviour.
A history of maltreatment is found in 80–90% of young offenders, and about one quarter of individuals with a history of severe maltreatment receive criminal convictions. Among the forensic psychiatric patients admitted to the REMS (Residential Facilities for the Enforcement of Security Measures), we have likewise observed a high prevalence of maltreatment, abuse, neglect, and other traumatic events, including those related to war and migratory pathways.
We have treated some patients showing psychotic-spectrum symptoms (delusions, hallucinations) that did not respond to pharmacological treatment (including clozapine and clozapine–first-generation antipsychotic combinations). Their condition improved only when trauma-oriented psychotherapy, such as EMDR or Narrative Exposure Therapy for Forensic Offender Rehabilitation (FORNET), was added to antipsychotic treatment.
This observation raises critical questions about the overlap between psychotic and post-traumatic symptoms in offending patients with severe early victimization histories, and hence about the link between schizophrenia spectrum disorders and complex post-traumatic stress disorder. In light of ongoing conflicts, rising geopolitical tensions, and their impact on migration, the early diagnosis and effective treatment of these conditions are of paramount importance from both a public health perspective and from the standpoint of security and the prevention of violent offenses

Ethnoterritorial features of paranoid schizophrenia with comorbid dependence on synthetic cannabinoids: Description of cases

N. Bokhan[1] and G. Selivanov[1,2]*

[1]Mental Health Research Institute, Tomsk and [2]Psychiatric Hospital of St. Nicholas the Chudotvorets, St. Petersburg, Russian Federation
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.232

Abstract: Introduction: it is indisputable that against the backdrop of the popularity of various addictions among patients with schizophrenia, a joint study of the clinical and pathomorphological deformation of two nosologically phenomena of paranoid schizophrenia and, depending on modern drugs that are gaining popularity, synthetic cannabinoids in various ethnoterritorial groups is relevant.
Objectives: to study the ethnoterritorial features of paranoid schizophrenia, comorbid with the abuse of synthetic cannabinoids, clinical dynamics, behaviour, and adaptation.
Methods: follow-up, clinical-psychopathological methods (PANS, SANS, CGI, MMPI, CGI, STAI, LSI, TPA, ICD-10), statistical (Python 3.11.0).
The results: of the examination of 193 patients (aged from 18 to 35 years): 142 – patients with paranoid schizophrenia dependent on synthetic cannabinoids F20.xx+F12.2xx and 51 – F20.xx without drug addiction. The study took place from 2018 to 2024 in the database of psychiatric institutions in Russia - Tomsk region, St. Petersburg, Noyabrsk and Nizhnevartovsk.
Conclusions: The leading position among patients with schizophrenia who use synthetic cannabinoids in the temperate continental climate zone of Russia was occupied by such ethnic groups as the hierarchy: Russians, Tatars; Uzbeks; Germans; Azerbaijanis, and Armenians.
The phenomenon of abuse of synthetic cannabinoids leads to the development of diseases. Persistent exogenous visual and delirious disorders are included in the complex of symptoms of exacerbation of schizophrenia; A new symptom of pseudohallucinoids appears - thought disorders of an associative (fantasy) disease that arose against the background of long-term exogenous (toxic) effects of the drug on the subject type, usually against the background of a primary endogenous schizophrenic process

CBS014

Violent behaviour as a psychopathological symptom: phenomenological distinction from general violence

L. Madeira

Universidade de Lisboa, Faculdade de Medicina, Lisboa, Portugal
doi: 10.1192/j.eurpsy.2025.233

Abstract: Violence is commonly conceptualized as a behavioural act, yet its phenomenological underpinnings reveal significant distinctions between its manifestations in psychopathological conditions and in the general population. This presentation explores how violent behaviour, when emerging as a symptom of psychiatric disorders, differs in its affective structure, intentionality, and embodiment from other forms of aggression. Drawing from phenomenological theories of emotions, we will examine how emotions such as anger, rage, resentment, and hatred manifest differently in psychopathology, particularly in psychotic states, mood disorders, and personality disorders. Emotions are not merely internal states but are lived experiences embedded in bodily spatiality, affecting contraction, expansion, and relationality. In psychopathological contexts, these emotions frequently exhibit disturbances in their anchoring point (what triggers them) and condensation area (where they settle), often leading to dysregulated, disproportionate, or delusionally overdetermined expressions of violence. By contrasting normative anger—typically goal-directed, normatively regulated, and socially embedded—with its pathological counterparts, we uncover crucial distinctions. In conditions such as paranoid psychosis, anger is fused with persecutory delusions, altering its structure from a transient reaction to an entrenched, self-perpetuating stance. Similarly, borderline personality disorder presents dysregulated anger as a core feature, where affective instability fosters reactive aggression that lacks modulation. In psychotic disorders, violent outbursts may emerge in a dissociative or hallucinatory framework, leading to actions detached from conventional interpersonal dynamics. Through a phenomenological analysis, we emphasize how aggressive emotions in psychopathology lack the typical integration of selfhood and social intelligibility, contributing to a distinct kind of violence —one that challenges legal and ethical frameworks regarding responsibility, intentionality, and treatment. By refining our understanding of these differences, we improve both clinical assessment and therapeutic interventions for patients at risk of violent behaviour.

Disclosure of Interest: None Declared

CBS015

Disturbance of Interaffectivity as a Precursor for Violence in Schizophrenia

S. Jerotic[1,2]

[1]Faculty of Medicine, University of Belgrade and [2]Clinic for Psychiatry, University Clinical Centre of Serbia, Belgrade, Serbia
doi: 10.1192/j.eurpsy.2025.234

Abstract: Schizophrenia is associated with impaired mentalizing abilities, often conceptualized through Theory of Mind (ToM) paradigms, which highlight deficits in understanding cognitive and affective mental states. Empirical findings suggest that affective ToM impairments reduce the likelihood of violence, while deficits in cognitive ToM may increase its propensity. However, phenomenological approaches challenge the primacy of ToM, suggesting that schizophrenia's core disturbance lies in the embodied self, specifically in the domain of interaffectivity—the pre-reflective, affective resonance between self and others.
Interaffectivity, rooted in early embodied interactions, forms the foundation of social and emotional connectedness. In schizophrenia, disruptions in this fundamental capacity result in a disconnection from the social environment and a breakdown in shared affective states. This disturbance may contribute to violence by

impairing empathic resonance and fostering misinterpretations of social cues.
Phenomenological approaches offer a critical lens for understanding these disturbances, emphasizing the embodied and relational aspects of schizophrenia. By shifting the focus from purely cognitive deficits to fundamental disruptions of interaffectivity, these approaches may provide a roadmap for developing interventions that address the precursors of violence, fostering a multifaceted understanding and management of schizophrenia.

Nosological problems in psychiatric diagnosis – Factitious disorder, Conversion, and Simulation

F. Novais[1]* and D. Telles-Correia

Faculdade de Medicina, Lisboa, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.235

Abstract: Diagnosing psychiatric conditions that involve the intentional or unconscious production of symptoms remains a significant challenge in clinical practice. This presentation examines a clinical case that highlights the difficulties in distinguishing between Factitious Disorder, Conversion Disorder, and Simulation. A 34-year-old woman was admitted with sudden onset of neurological symptoms, including pseudo epileptic crises. Her symptoms fluctuated inconsistently with clinical observation and failed to correlate with established neurological patterns, raising the suspicion of Conversion Disorder. However, further investigation revealed inconsistencies in her medical history and a pattern of seeking unnecessary treatments, suggesting the possibility of Factitious Disorder. Additionally, external incentives, such as the potential for financial compensation, prompted consideration of Simulation. The case presents a diagnostic dilemma that underscores the overlapping features of these conditions.
Neuroimaging may provide valuable insights into the case, supporting the exclusion of neurological pathologies but also subtle changes in brain activity in the areas involved in emotional regulation and self-representation, which may suggest the involvement of underlying psychological factors common in both Conversion and Factitious Disorder.
This case exemplifies the critical nosological challenges in differentiating between Factitious Disorder, Conversion Disorder, and Simulation. It highlights the importance of a comprehensive clinical approach, including neuroimaging, thorough psychological assessment, and consideration of psychosocial factors. The discussion aims to deepen understanding of these complex disorders and promote more accurate and nuanced diagnostic practices in psychiatry.

Neuronal synaptic autoantibodies and PsycHosis: Prognostic factors for the diagnosis of autoimmune encephalitis in patients with psychotic spectrum disorders -The PHLAMES Study

A. Pigoni

Neuroscience, IRCCS Fondazione Ca Granda Policlinico Hospital, Milan, Italy
doi: 10.1192/j.eurpsy.2025.236

Abstract: Background: The recent years witnessed an increase in the knowledge regarding autoimmune encephalitis (AE). These autoimmune entities often present with mixed psychiatric and neurologic features and in up to 4% of the cases the presentation is purely psychiatric. The diagnosis can be made only through the discovery of Neuronal Surface Autoantibodies (NSAbs) in the Cerebro Spinal Fluid, but symptoms and signs of possible and probable diagnosis have been described (Pollack et al., 2020). However, NSAbs can be found also in peripheral blood in various percentage of patients. The role of these antibodies in psychiatric patients is yet not known.
The PHLAMES study aims at evaluating first episode psychosis (FEP) patients for signs and symptoms of AE in a psychiatric setting, with the double objective of assessing the diagnosis of AE and the role of circulating NSAbs in psychiatric patients, through clinical evaluation, biological samples, and neuroimaging.
Methods: In the PHLAMES study, all patients with FEP (<6 months from the onset) were tested with a diagnostic algorithm for signs or symptoms of AE. A complete psychiatric and neurologic assessment was performed; cognitive tests were administered. All patients underwent blood sample to test for circulating autoantibodies against SNC structures.
A subsample also underwent MRI, including gadolinium contrast. Analyses compared patients testing positive for serum NSAbs (NSAbs-POS) to those tested negative (NSAbs-Neg).
Results: 12.8% of the patients tested positive for serum NSAbs (NSAbs-POS). No difference in terms of age, sex, BMI, years od education, and ethnicity was found between groups.
Regarding the neurologic variables, NSAbs-POS significantly showed more memory deficits, parkinsonism signs, and speech disorders ($p<0.001$), compared to NSAbs-NEG patients. Similarly, NSAbs-POS patients presented a significant in TMT-A, Raven, and RAVLT scores ($p<0.05$) compared to NSAbs-NEG. Finally, NSAbs-POS patients presented an increased score at PANSS "Somatic implication" item and a reduced score at PANSS "Insight" ($p<0.05$) items, suggesting a higher concern of these patients regarding their help and a greater awareness of their condition.
Regarding MRI, differences are present between groups, both on structural and on contrasted images.
Discussion: Our preliminary findings suggest the possibility that NSAbs-POS patients might represent a subpopulation of FEP with specific characteristics. These results are preliminary and need a confirmation in bigger samples, but they might represent a step towards the identification of clinically meaningful subgroups in FEP defined through an easy and not invasive test, helping to dissect the heterogeneity of psychiatric disorders and moving towards precision psychiatry.

CBS018

Differential diagnosis between somatic and psychiatric disorders based on laboratory tests integrated with neuroimaging

K. Krysta

Department of Rehabilitation Psychiatry, Medical University of Silesia, Katowice, Poland
doi: 10.1192/j.eurpsy.2025.237

Abstract: The differentiation between somatic and psychiatric disorders presents a significant challenge in clinical practice due to overlapping symptomatology and complex etiologies. This abstract proposes an integrated approach utilizing laboratory tests and neuroimaging techniques to enhance diagnostic accuracy and improve patient outcomes. Somatic disorders, characterized by physical symptoms with identifiable organic causes, often mimic psychiatric conditions, leading to misdiagnosis and inappropriate treatment. Laboratory evaluations play a crucial role in ruling out medical conditions that may present with psychiatric-like symptoms. Thyroid function tests, vitamin B12 level assessments, and screening for infections are vital in this process. Routine blood tests further aid in detecting systemic conditions contributing to psychiatric presentations. Neuroimaging techniques offer visual insights into brain structure and function, facilitating the differentiation between psychiatric and neurological conditions. Structural imaging modalities like MRI and CT scans can reveal abnormalities such as tumors or lesions. Functional imaging, including PET and SPECT scans, assesses cerebral metabolism and blood flow, identifying anomalies associated with specific psychiatric disorders. Integrating laboratory tests with neuroimaging significantly enhances diagnostic precision. In suspected dementia cases, for instance, laboratory tests can exclude metabolic or infectious causes, while neuroimaging can identify characteristic patterns of Alzheimer's disease or vascular dementia. This combined approach ensures a thorough evaluation, reducing misdiagnosis and facilitating targeted treatment strategies. Clinical studies have demonstrated the efficacy of this integrated approach in improving diagnostic accuracy for conditions like major depressive disorder and bipolar disorder. Functional neuroimaging has also proven instrumental in distinguishing between psychiatric disorders and neurological conditions such as epilepsy. Despite its advantages, this approach faces challenges, including cost, availability, and the need for standardized interpretation protocols. Future directions include advancements in neuroimaging accessibility, research into novel biomarkers, and the integration of artificial intelligence for enhanced diagnostic accuracy and personalized treatment planning. In conclusion, integrating laboratory tests with neuroimaging represents a significant advancement in the differential diagnosis of somatic and psychiatric disorders. This comprehensive approach facilitates accurate diagnosis, ensuring patients receive appropriate and effective treatment, ultimately leading to improved patient outcomes.

History and definitions of AI

E. Chumakov

Department of Psychiatry and Addiction, St Petersburg State University, St Petersburg, Russian Federation
doi: 10.1192/j.eurpsy.2025.238

Abstract: Artificial Intelligence (AI) has evolved from philosophical musings to a crucial component of modern technology. The concept of using computer technology to simulate thinking and intelligent behavior was first described by Alan Turing in 1950. The Dartmouth Conference in 1956 marked a pivotal moment, coining the term "artificial intelligence" and fostering interdisciplinary collaboration. Further contributions to the development of AI theory were made by scholars such as John McCarthy, Valerie Barr, Edward Feigenbaum, Claude Shannon and others. The concept of creating AI is to form a system that would be able to operate autonomously, solving intellectual tasks in a manner similar to human cognitive processes. This is achieved by using algorithms that are translated into computer code containing instructions for quickly analyzing and transforming data into conclusions, information, or other outputs. Throughout the subsequent decades, AI experienced cycles of optimism and disillusionment, known as "AI winters," primarily due to unmet expectations regarding computational capabilities and practical applications. The resurgence of AI in the 21st century can be attributed to breakthroughs in machine learning, especially deep learning, and the availability of vast datasets and increased computational power. Today, AI is defined broadly as the capability of a machine to imitate intelligent human behavior, encompassing a range of subfields including natural language processing, robotics, and computer vision. As AI continues to evolve, its definitions are adapted to address ethical considerations and the implications of autonomy in decision-making systems. Current discourse often examines AI not only as a technological phenomenon but also as a sociocultural force, raising questions about accountability, bias, and the future of work. This presentation will reflect the complex path of AI development and the shifting paradigms that define its scope and impact on modern society.

What can AI do for mental health care

U. Volpe

Deaprtment of Clinical Neurosciences/DIMSC, Università Politecnica delle Marche, Ancona, Italy
doi: 10.1192/j.eurpsy.2025.239

Abstract: Artificial intelligence (AI) is reshaping mental health care by improving diagnosis, treatment, and patient support. AI-driven tools streamline administrative tasks, enhance clinical documentation, contribute to medical education, and enable continuous symptom monitoring. Additionally, AI augments text-based support programs, offering accessible psychological interventions. However, while AI applications have been assessed for perceived

empathy, their impact on clinical outcomes remains uncertain, highlighting the need for evidence-based implementation.
AI can immediately enhance efficiency in routine clinical tasks. Automation optimizes billing processes and reduces clerical burdens, allowing clinicians to focus more on patient care. In clinical documentation, AI-powered transcription and natural language processing (NLP) help generate structured medical records. AI also supports medical education by offering adaptive learning, personalized training, and real-time feedback through large-scale data analysis.
Beyond administrative support, AI plays a role in patient monitoring and early intervention. AI algorithms analyze speech, facial expressions, and behavioral data from smartphones and wearables, detecting mood fluctuations and early psychiatric symptoms. This real-time analysis can facilitate timely interventions and improve overall mental health care. Additionally, AI-powered chatbots and virtual therapists are increasingly used in digital mental health services, providing immediate, text-based psychological support. However, rigorous studies are needed to assess their effectiveness in improving clinical outcomes. A well-established framework for technology evaluation in mental health highlights five key areas for development: equity, privacy, evidence, clinical engagement, and interoperability. Addressing these factors is crucial to ensuring AI-driven solutions are accessible, secure, scientifically validated, clinically integrated, and capable of working across diverse health systems. By prioritizing these advancements, AI can move from theoretical promise to practical application, meaningfully improving mental health care delivery.

AI solutions for adolescent psychiatry

T. Gargot

Child and Adolescent Psychiatry, University Hospital Tours, Tours, France
doi: 10.1192/j.eurpsy.2025.240

Abstract: There is a potential for new technologies in mental health and psychiatry. Artificial intelligence enables the design models that categorize different groups and predict different prognosis trajectories.
Natural language processing enables to use classical text data from electronic health records, for instance, to detect suicide trends and their risk factors (Bey et al., 2024). This opens new perspectives in the analysis of large Electronic Health Records databases.
Artificial intelligence can extract and combine new features, like posture, physiological signal of stress and facial expression. This could be particularly important to bypass insight development in children of adolescents (Bourvis et al., 2021) while taking the opportunity of early management. This could help to optimize exposure therapy (Mahmoudi-Nejad et al., 2024), detect tantrums in non-verbal children (Cano et al., 2024) or even improve motivation for physical activity (Nuss et al., 2020).
In motion assessment, we could detect motor assessment difficulties in children with autism from typical counterparts (Gargot et al., 2022). We can also automatically detect writing difficulties (Agarwal et al, 2023).
However, AI struggles with an interpretability problem (black box). Their model are complex, the features extracted are not always obvious (Minh et al, 2021 ; Linardatos et al, 2020) .
Fine motor skills classic signal processing allows to tailor specific exercises to reeducate children with writing difficulties (Gargot et al., 2021).
Digital psychiatry however is impeded by poor user experience (Witteman et al., 2011), complex market models (Gollier-Briant et al., 2024).

AI for psychiatric training and education

D. Eraslan[1]* and P. Thomann on behalf of Digital Psychiatry

Psychiatry, SRH Klinikum Karlsbad Langensteinbach, Karlsbad, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.241

Abstract: Artificial intelligence (AI) is transforming psychiatric training and education by enhancing diagnostic accuracy, improving therapeutic decision-making, and personalizing learning experiences for trainees. AI-driven simulations, virtual patients, and natural language processing (NLP)-based assessments allow for more effective skill development in psychiatric diagnosis and psychotherapy. Machine learning models provide evidence-based guidance, reinforcing clinical reasoning and treatment strategies. Ethical considerations, including patient confidentiality and bias mitigation, remain central to AI implementation in training. This session explores the latest advancements in AI-driven psychiatric education, discussing practical applications, challenges, and future directions for integrating AI into clinical training programs.
Keywords: AI, psychiatry, education, machine learning, clinical training

Cultural competence in forensic psychiatry

K. Goethals

Antwerp University Hospital, Antwerp, Belgium
doi: 10.1192/j.eurpsy.2025.242

Abstract: In this paper several issues about cultural competence will be addressed, such as assumptions, Mason's five progressive steps and learning needs of professionals. The notion of cultural

competence combines an understanding of different belief systems, good communication skills (including highly specialist skills such as the communication of internal emotional states, and the cultural adaptation of treatment models and therapies. Professionals can measure theircompetence on a continuum developed by James Mason. His five progressive steps are: cultural destructiveness, incapacity, blindness, pre-competence, and competence. Next, the mental health needs of refugees will be discussed, especially for those who are at risk to become violent offenders. For example, some types of environmental and psychosocial stressors that refugees may experience day-to-day. Some of the cultural and attitudinal factors should be taken into account when working with refugees and wider communities. Finally, educational needs for trainees in (forensic) psychiatry and (forensic) psychiatrists will be highlighted. Knowledge about culture, ethnicity, race, religion, and identity is hereby crucial. Reflections will be made on the presented case.

How to manage sleep in women with ADHD during (peri)menopause?

D. Wynchank

ISP ADHD bij volwassenen, PsyQ, The Hague, Netherlands
doi: 10.1192/j.eurpsy.2025.243

Abstract: For women navigating both ADHD and the (peri)menopausal transition, sleep problems are a common and significant hurdle. This presentation explores effective ways to improve sleep for (peri)menopausal women with ADHD, drawing on research into hormonal, non-hormonal, and behavioural approaches. ADHD can make sleep difficult, contributing to issues like delayed sleep phase, insomnia, and restless legs syndrome/periodic limb movement disorder (RLS/PLMD), with roughly 60% of adults with ADHD screening positive for a sleep disorder. Research indicates that adults with ADHD often take longer to fall asleep and experience more sleep-related challenges than those without ADHD. Similarly, (peri)menopausal women often struggle with sleep disturbances, including poor sleep quality and increased restless legs symptoms. Considering that (peri)menopausal symptoms can also impact cognitive function, addressing these symptoms may lead to better sleep. Menopausal Replacement Therapy (MRT) may be beneficial, especially for women with vasomotor symptoms, as it can improve sleep quality and reduce nighttime awakenings. In addition, multiple studies suggest that bioidentical progesterone can improve sleep quality in perimenopausal women. We will also discuss non-hormonal options and behavioural strategies like cognitive behavioural therapy, exercise, and mindfulness techniques. With a significant percentage of women with ADHD diagnosed with a sleep disorder and prescribed sleep medication, and a similar percentage of perimenopausal women experiencing sleep disturbances, a personalised, integrated approach is key. This includes fine-tuning ADHD medication, managing any co-existing mood issues, and customising treatments to fit individual needs.

Ethical tensions created by AI in the mental health sector

J. Wise

CNWL NHS Foundation Trust, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.244

Abstract: Artifical Intelligecne is sold as a magic solution, and yet its inscrutability poses a major problem. Who is the source of the knowledge? Who is accountable? Who is responsible? Who can edit or train it? Has it been trained on copyrighted material? If so, have the owners been compensated? If not, is it culturally relevant? Has the 'black box' aspect been addressed? Whether a provider of knowledge, a clinical decison aid or a decsion maker, troubling issues arise that as yet have not been solved by legisaltion or the market. We shall explore potential benefits, solutions, and actual problems with real world cases that shed light on where AI may take us, and where we may need constarints that lie beyond medical ethics.

Early Onset Psychosis

C. U. Correll[1,2]

[1]Child and Adolescent Psychiatry at Charité – University Medicine, Charité University Medicine - Berlin, Berlin, Germany and [2]Psychiatry and Molecular Medicine, Zucker School of Medicine at Hofstra/Northwell, Hemstead, United States
doi: 10.1192/j.eurpsy.2025.191

Abstract: Early onset psychosis and, especially, early-onset schizophrenia (EOS), defined as the onset of psychotic symptoms before

the age of 18, represent severe and frequently disabling conditions with adverse long-term functional consequences. Effective pharmacological treatment is critical to mitigating symptom progression, reducing relapse, and improving long-term outcomes. This presentation provides an update on current evidence-based pharmacological strategies for EOS, with a focus on efficacy, safety, and emerging treatments.

Second-generation antipsychotics (SGAs), such as aripiprazole, quetiapine, paliperidone, and risperidone, remain the mainstay of treatment, with lurasidone and brexpiprazole showing positive results in more recent studies. While olanzapine is clearly an effective SGA, its more pronounced cardiometabolic side effects have relegated olanzapine more to a second-line antipsychotic when other SGAs are ineffective. Thus, comparative efficacy, side effect profiles, and long-term metabolic risks are relevant when choosing among individual agents. The role of clozapine for treatment-resistant EOS and considerations regarding polypharmacy are relevant, given that EOS is one of the most reliable risk factors for treatment-resistant schizophrenia .

Long-acting injectable antipsychotics (LAIs) have not been explored in randomized trials so far, but are an important treatment tool, given the widespread non-adherence risk, which is even higher earlier in the illness. Novel mechanisms, including cholinergic muscarinic agonist treatments, recently approved for the first time for adults with schizophrenia, which address presynaptic hyperdopaminergia and in a highly selective fashion, need to be explored in EOS in the future. Additionally, the importance of early intervention strategies and adjunctive nonpharmacological and pharmacological treatments, e.g., mood stabilizers, antidepressants for specific domains of schizophrenia and for comorbid conditions, as well as best practices for transition into the adult psychiatry sector require further study.

In summary, treatment selection for youth with EOS should balance short-term as well as long-term efficacy considerations and safety concerns. While pharmacological advancements in EOS generally lag behind advances in adults, innovations are hoped to also reach EOS. More individualized and measurement-based approaches needed to be explored in both research settings and clinical care aiming at optimizing the pharmacological management for individuals living with EOS.

French psychiatrists' concerns about assisted death

E. Olie

Department of Emergency Psychiatry and Acute Care, Lapeyronie Hospital, CHU Montpellier, Montpellier, France
doi: 10.1192/j.eurpsy.2025.192

Abstract: A bill on euthanasia and assisted suicide is currently under discussion in France. It proposes that only competent adults suffering from a serious and incurable condition that threatens their life in the medium term, or who are in an advanced or terminal phase, and experiencing unbearable physical or psychological suffering—either refractory to treatment or considered unbearable in the absence of treatment—may request medical assistance in dying (MAiD). However, French psychiatrists have expressed concerns about the bill, as it does not mandate a psychiatric evaluation, despite the high prevalence of mental disorders, including depression, in the general population. These disorders are even more frequent in end-of-life conditions and can significantly impact decision-making capacity and the wish to die. Depression, a common comorbidity in cancer—the leading cause of MAiD requests—affects approximately 15% of cancer patients but is often underdiagnosed and undertreated. The bill also raises concerns regarding its implications for suicide prevention. Some MAiD requests may stem from treatable psychiatric conditions rather than a well-considered end-of-life choice. Furthermore, a proposed obstruction offense could potentially criminalize suicide prevention efforts, complicating the role of mental health professionals. Uniquely, the French bill allows a third party chosen by the patient to administer the lethal substance, a provision not found in any other country. This raises significant ethical and psychological concerns regarding the emotional burden on the designated individual, who may experience distress, guilt, or long-term psychological repercussions from actively participating in assisted dying. Finally, the possibility of future expansion to include psychiatric-only indications, as seen in other countries, remains a critical issue requiring careful ethical and medical scrutiny.

What forms of framing can be found in the Flemish media in a jury trial about euthanasia for psychological suffering?

K. Catthoor[1,2,3]

[1]CAPRI, University of Antwerp; [2]PZ Stuivenberg, Ziekenhuis aan de Stroom, Antwerp and [3]Flemish Association of Psychiatry, Kortenberg, Belgium
doi: 10.1192/j.eurpsy.2025.193

Abstract: The Flemish Association of Psychiatry developed due care guidelines for medical assisted dying in cases of severe and unbearable psychiatric suffering, which were adopted by the Order

of Physicians. In principle, there are therefore more than enough well-known recommendations on how to handle a request for termination of life from a patient with psychiatric issues.
Nevertheless, occasionally something goes wrong due to misinterpretation of the legal criteria or due to careless actions by the consulting or performing physician.
In 2010, a female patient died by euthanasia because of unbearable mental suffering, which was unacceptable for her family. The family decided to initiate a court case to have the inaccuracies in the decision-making process and the execution of the euthanasia evaluated by a judge. In 2020, three involved doctors, including a psychiatrist, were prosecuted for this euthanasia. An analysis of the court case and the media coverage of this case will be discussed.

Euthanasia and assisted death from a Spanish perspective

M. Martin-Carrasco

Psychiatry, Clinica Psiquiatrica Padre Menni, Pamplona, Spain
doi: 10.1192/j.eurpsy.2025.194

Abstract: Medical assistance in dying is an increasingly available option for people suffering (solely) from psychiatric disorders. Initially promoted to alleviate the suffering of terminally ill people, a growing number of jurisdictions are adopting it for any cause of intractable and severe suffering, including mental disorders. Today, the BENELUX countries, along with Spain and Switzerland, explicitly authorise it or allow it de facto. Other countries, such as Canada, are considering implementing it. Although in jurisdictions where it is permitted it is argued that it is discriminatory not to consider mental suffering as sufficient cause, there are reasons for concern. The procedure is likely to be used as an alternative to care, that is, as a gentler form of suicide, more commonly used by women. The long-term impact of this practice must be considered, as it sends the message that mental illnesses may not be curable, and that it is not worth the effort to treat them, or to demand the necessary care. Furthermore, all of these factors must be considered in the context of highly stigmatized disorders to which clearly scarce resources are allocated.

Lessons from Belgium: Physician-assisted dying for (neuro)psychiatric suffering after 23 years of Belgian euthanasia legislation

J. Vandenberghe[1,2]

[1]Dpt Neurosciences, Psychiatry Research Group, University KU Leuven and [2]Adult Psychiatry, University Psychiatric Center KU Leuven, Leuven, Belgium
doi: 10.1192/j.eurpsy.2025.195

Abstract: In 2002, the euthanasia law was voted in Belgian parliament, depenalising physician-assisted dying under certain conditions for irremediable physical or mental suffering caused by an incurable condition for which all therapeutic options have been exhausted. The euthanasia request needs to be repeated, well-considered and voluntary and the patient should be competent. If the patient is not in a terminal condition, there should be at least one month between the written request and the euthanasia and three independent physicians have to be involved in the evaluation. Psychiatric suffering was not excluded in the law, but there is discussion whether the possibility of psychiatric euthanasia was intended by the legislator. In the first years after the euthanasia law, psychiatric euthanasia was limited to a few cases, but then rose to a mean of 25 cases per year. There was a peak in 2013 of 54 cases, but after 2013 there was no more increasing trend.
In 2017, the Flemish Association for Psychiatry issued an advice regarding due diligence in psychiatric euthanasia. Controversy regarding psychiatric euthanasia kept stirring the public debate, especially after one court case in which a psychiatrist and general physician were accused and acquitted after a psychiatric euthanasia. Another prominent topic in the public debate in Belgium is broadening the euthanasia law for advanced dementia based on an advance directive. Now euthanasia is only possible in the earlier stages of neurodegenerative disease, when competence is still sufficiently intact.

Current situation in Europe – different perspectives from Poland

J. Samochowiec

Department of Psychiatry, Pomeranian Medical University, Szczecin, Poland
doi: 10.1192/j.eurpsy.2025.196

Abstract: The presence of large numbers of Ukrainians looking for refuge in Poland is a new experience for Poles. The ongoing war and the uncertainty of the situation of those displaced may cause anxiety and lead to stressful reactions, exacerbated by endlessly circulating information on hostilities. Therefore, the sense of security may be threatened not only among Ukrainians who have fled to Poland, but also among people who support Ukrainians, who offer them help and shelter. Prolonged support, if not accompanied by proper selfcare can increase the risk of burnout as well as lead to distressful emotional states, such as a feeling of helplessness, reluctance to provide further help, or even demonstrate hostility. The Polish government and polish NGO's have pledged to help refugees from Ukraine, including the provision of mental health care. Raising awareness of the whole society and training employees from sectors other than medical may help in the proper protection of mental health of refugees and the people supporting them. Dividing the organization of mental health care into the four levels (Intervention Pyramid (Inter Agency Standing Committee, 2007)and offering support depending on the needs, ranging from building a basic sense of security, acceptance, and support for meeting the needs of refugees, to the level of highly specialized psychological and psychiatric assistance, enables the use of the resources of the entire society and specialists in an appropriate manner. By activating refugees themselves and training employees and volunteers of

various sectors and fields of support, the goal of mental health promotion is spread across many environments, which mental health professionals themselves cannot cope with in these new, difficult conditions.

Workshop of the Task Force on Migration and Mental Health

S. -.- Bäärnhielm on behalf of Task Force on Migration and Mental Health and Workshop of the Task Force on Migration and Mental Health

Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden
doi: 10.1192/j.eurpsy.2025.197

Abstract: Introduction: Sweden has a long history as a host country for refugees. In recent years there has been a shift from being one of the most generous host countries in Europe to one of the most restrictive. In Sweden, refugees with a residence permit have a full right to care, but asylum seekers and undocumented migrants only have a right to care that cannot be deferred. Despite relatively good formal access to mental health care, and so far, the availability of free language interpreters, refugees face barriers to and within mental health care.
Aims: To give a brief overview of the current challenges for mental health care in Sweden and the work on solutions for people on the move.
Research methods: Ongoing research and clinical development are summarised in parallel with the identification of challenges.
Findings: A complex picture of the development and challenges of mental health care for people on the move in a situation of increasing social pressure on refugees is described.
Conclusions: There is a need for equal treatment of people on the move without discrimination and exclusion.

Current situation in Europe – different perspectives

M. Schouler-Ocak* and Task Force on Migration and Mental Health

Psychiatry and Psychotherapy, Charité - Universitätsmedizin Berlin, Berlin, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.198

Abstract: Germany is one of the countries that has taken in a large number of refugees. Around 2.25 million now have recognised protection status in Germany. In addition, Germany has taken in over 1,215,048 refugees from Ukraine. All of these people are very vulnerable refugees who are exposed to many risk and stress factors before, during and after their migration. As a result, they have a high prevalence of mental disorders such as post-traumatic stress disorder (PTSD), depression, anxiety, substance use and persistent grief disorder. At the same time, refugees face numerous barriers to accessing medical care, such as language and cultural barriers, administrative barriers, structural, institutional and interpersonal discrimination and racism. There is also unequal treatment in Germany between refugees from Ukraine and other regions of the world. In addition, healthcare provision has recently been tightened due to changes in the Asylum Seekers' Benefits Act. This presentation will focus on the sitaution in Germany and discuss üossible solutions.

Seeing Affective and Psychotic Disorders through Addictions: Case Studies to Review the Challenges for the Survival of both "the Patient on the Edge" and "Therapeutic Alliance"

B. D. Ulug

Psychiatry, Hacettepe University School of Medicine, Ankara, Türkiye
doi: 10.1192/j.eurpsy.2025.199

Abstract: Comorbidities in addiction: It is a rule rather than an exception. The story starts in childhood; even before, in infancy, and may be in prenatal life. The dimensional traits have already been there, existing obviously far before any DSM-5 diagnosis. Among these traits, the developmental features named as stress sensitivity, impulsivity and emotion dysregulation are the leading ones. Comorbidity research addressed childhood abuse, neglect or other childhood adverse experiences as a definite risk factor for adolescence and adult mental disorders, particularly substance use disorders. Developmental and environmental adversities in a mutually amplifying pattern make a vicious cycle in which the individual finally finds an illusionary exit, a pathway to addiction. This presentation aims to discuss the complexities and challenges for the diagnosis and treatment of cases presenting with ASUD (alcohol and substance use disorders) and comorbid neurodevelopmental and affective or psychotic disorders . The history as well as the life and the management charts of the patients are reviewed in the light of information collected during the follow-up years revealing significant alterations with regard to diagnoses and therapeutic approaches. A specific focus of the case studies will be the missed or mis-diagnoses, and the impact of them on the treatment courses and the outcomes. One of the case studies with an eight year follow-up period, shows ADHD traits, alcohol use disorder, affective disorder and a later emerging severe stimulant use disorder. The second case with a similar ADHD history, presents with a stimulant use disorder, co-occuring with a severe psychotic disorder, that has been mis-diagnosed as schizophrenia. The life and management charts of the studied cases convey the drawbacks of the diagnostic difficulties, the treatment failures and the implication of efficient therapeutic strategies.
The challenges faced by clinicians due to co-occuring disorders that have become a common practice for addiction professionals. should be managed by transdiagnostic and integrative modalities. While big data or empirical large datasets can have their own limitations to help the practitioner for overcoming such complexities of real world situations, as stated in Stein's article (2022, Psychiatric diagnosis and treatment in the 21st century: paradigm

shifts versus incremental integration) "the age-old single-case studies, may sometimes provide clinical insights that outweigh those from big data analyses."

Neurodevelopmental Challenges: Dealing with ADHD and Addictions

A. Schellekens

Psychiatry, Radboudumc, Nijmegen, Netherlands
doi: 10.1192/j.eurpsy.2025.200

Abstract: Attention Deficit Hyperactivity Disorder (ADHD) and Substance Use Disorders (SUD) frequently co-occur. Patients with this comorbidity report poorer qualtiy of life, and have worse treatment outcomes for both disorders, including high relapse rates of the SUD. In this case based discussion, clinical dilemma's in the diagnosis and treatment of patients with this comorbidity will be discussed. Recent findings of the International Collaboration on ADHD and Substance Abuse (ICASA) will be used as background, including findings from ICASA's most recent work: the longitudinal International Naturalistic Cohort Study of ADHD and SUD (INCAS), where nearly 600 patients with both ADHD and SUD in treatment were followed for nine months. In addition, ICASA's consensus statements on diagnosis and treatment of co-occurring ADHD and SUD in youths and adults will be shortly discussed.

Discussion on the case from neurodevelopmental and transdiagnostic perspectives

A. Lingford-Hughes

Psychiatry, Imperial College London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.201

Abstract: During the workshop about this complex case, I will discuss aspects of the case and the challenges the individual has faced from a neurodevelopmental and transdiagnostic perspective. It is the norm that those presenting for treatment or support with problematic drug/alcohol use will also have co-occurring neurodevelopmental, mental and physical health traits or disorders. Their relationships are often complex and ingrained. It is generally unhelpful to consider such complexity in terms of 'primary' vs 'secondary' as this may lead to exclusion from some services. For instance, someone with depression and problematic alcohol use may not be seen by psychiatric services or psychologists due to their drinking and an 'addiction' service may not have sufficient mental health expertise for managing their depression. Such 'silos' are common and need to be addressed through better understanding of the relationships between problematic drug/alcohol use and co-occurring neurodevelopmental, mental and physical health traits or disorders, through better training of health and social care staff and reducing stigma.

Neurostimulation in Addictions: a retrospective study in patients with Cocaine Use Disorder undergoing a rTMS protocol

A. Gual[1,2*] and P. Lusilla[3]

[1]Health and Addictions Research Group, Fundació Clínic - Idibaps; [2]Centre Bonanova and [3]Psychiatry Department, Hospital Vall d'Hebron, Barcelona, Spain

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.202

Abstract: There are clear unmet medical needs in the treatment of Cocaine Use Disorder (CUD), since there are no pharmacological treatments approved. The neurobiological circuitry of addiction has been described in recent years, and it provides a solid rationale to target specific brain regions to treat addictive behaviors, including CUD. The stimulation of the left Dorsolateral Prefrontal Cortex (DLPFC) with repetitive transcranial magnetic stimulation (rTMS) has proved to reduce craving for various drugs, including cocaine. We present the results of a retrospective study performed in a private setting with 93 patients with CUD, who were treated with rTMS following the protocol from Terraneo et al. In 12 weeks patients received 32 sessions of 2400 pulses (100% MT; 10 Hz; 60 pulses per train, 15 seconds interval; 40 trains per session), for a total of 76800 pulses.

The main outcome was total abstinence of cocaine (self-reported plus urinalysis). Abstinence rates at days 30, 60 and 90 were 55,9%; 40,8%; and 34,4% respectively.

Psychiatric comorbidities (insomnia, depression and anxiety) were also assessed with validated questionnaires. Drop-out was directly related to recent cocaine use, but initial levels of psychological distress did not predict drop-out.

No relevant side effects were reported. Mild and transient headache was reported by a few patients after the first session.

In conclusion rTMS was well tolerated, drop out rates were high and 34% of the patients remained abstinent after the 90 days treatment period.

Connectivity-guided iTBS versus rTMS for treatment-resistant depression: Results from the BRIGhTMIND Study

M. Abdelghani

TMS Service, North London NHS Foundation Trust, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.204

Abstract: Treatment-resistant depression (TRD) remains a major clinical challenge, necessitating novel and more effective therapeutic approaches. The BRIGhTMIND study is the largest transcranial magnetic stimulation (TMS) clinical trial conducted in the UK. This multicentre, randomised controlled trial compares the efficacy of connectivity-guided intermittent theta burst stimulation (iTBS) with standard repetitive transcranial magnetic stimulation (rTMS) in patients with TRD. This talk will present key findings from the study, including response and remission rates, reported side effects, and key differences between the novel iTBS protocol tested and the conventional rTMS protocol used as the control condition. Additionally, we will explore the clinical implications of using functional connectivity to optimise stimulation targets. The results contribute to the growing evidence supporting TMS as an effective intervention for TRD and offer insights into the future of precision psychiatry in brain stimulation.

WS016

Transmagnetic Stimulation in Special Situations: Is Its Use Safe During Pregnancy?

P. Lusilla

Psiquiatria, Hospital Universitario Vall d'Hebron, Barcelona, Spain
doi: 10.1192/j.eurpsy.2025.205

Abstract: Transcranial Magnetic Stimulation (TMS) is a non-invasive procedure that uses magnetic fields to stimulate nerve cells in the brain. It is primarily used to treat depression and other mental health conditions. When it comes to the safety of TMS during pregnancy, the current evidence is limited but generally suggests that it may be a safer alternative to medications that could potentially harm the fetus. Several small studies and case reports have indicated that TMS does not appear to pose significant risks to the pregnant woman or the fetus. However, the data is not extensive, and more research is needed to fully understand the implications. The procedure is typically avoided in the first trimester unless absolutely necessary, as this is a critical period for fetal development. In summary, while TMS is considered relatively safe during pregnancy, especially compared to some pharmacological treatments, it should only be used when the potential benefits outweigh the risks, and under the close supervision of a healthcare provider. Pregnant women considering TMS should discuss their specific situation with their doctor to make an informed decision.

The Portrayal of Psychosis and Delusion in Film History (1895–1930)

D. Henkel

Institute for the History of Medicine and Medical Ethics, University of Cologne, Cologne, Germany
doi: 10.1192/j.eurpsy.2025.206

Abstract: The turn of the century was an important era for the field of psychiatry. Influential physicians such as Sigmund Freud (1856-1939) or Eugen Bleuler (1857-1939) made headlines and new theories on the pathogenesis of psychological disorders emerged with the psychoanalytic approach – the whole field seemed in a state of transition. But did this modern image correspond to how two of psychiatry's most famous conditions – psychoses and delusions – where framed in the mass media of film? Surprisingly, there are no systematic works on these question, neither by medical nor film historians. This lecture tries to close this gap and, for the first time in international research, provides a systematic overview of the representation of the theme in silent cinema. With the aim of sketching a representative image, 36 works portraying psychoses and / or delusions were identified and, among other things,

historically classified, analyzed and evaluated for medical correctness. In summary, it is shown that the early film depicts the condition in a highly ambivalent way, from dangerous and untreatable Insanity to curable illness, thereby reflecting one of the most significant transitions in the history of the understanding delusional symptoms. The presented therapy methods – e. g. psychoanalysis, hypnotherapy, electrotherapy, water therapy and even music therapy –, thus rarely utilized, appear highly modern, while the depiction of the patients seems more influenced by the shadows of the past. Accompanied by scenes from representative works such as *The Other* (1913), *Wolf Blood* (1925), *Shadows* (1923) or the German classic *The Cabinet of Dr. Caligari* (1920), the presentation aims to illustrate all these characteristics of the early 'psychosis und delusion film' and explores the important role of cinema as a source of medical history.

Cinema Therapy: From the Silent Film Era to the Present Day

M. Poltrum[1]* and M. Poltrumn

Faculty of Psychotherapy Science, Sigmund-Freud-University, Vienna, Austria
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.207

Abstract: Under the rubric of cinema therapy, or movie therapy, research has been undertaken for some time to test the effect of films in different therapeutic settings and with different patient groups. Taking a closer look at the history of film therapy, it becomes apparent that at the time of the silent film, there was already a medical discourse on the effect of films in a therapeutic context. In this lecture, principal philosophical-therapeutic elements of consideration regarding cinema therapy are presented along with historical and current discourses; the most important publications are indicated; and the author's own cinema-therapeutic models, experiences and reflections are reported. In addition, selected case studies show how films can be utilized in a clinical context and which effects and unwanted side effects result from film therapy. The final focus of the lecture is on films that depict psychotherapy, love films, and films that address the phenomena of intoxication, ecstasy, and addiction, and how these have been applied by the author in the inpatient treatment of addicts.

'Film is psychosis': filmmakers with lived experience

S. Anderson

Psychotherapy Science, Sigmund Freud Private University Vienna, Vienna, Austria
doi: 10.1192/j.eurpsy.2025.208

Abstract: The presentation juxtaposes the practice of psychiatry with the creative processes involved in filmmaking. It proposes a correlation between the representation of reality in film, and the processing of visual information. It is informed by autobiographical case study films written and directed by individuals with experience of psychosis. In-depth analysis of film conventions employed by filmmakers with experience of psychosis indicate the potential benefits of further research into collaboration with, and contributions from, those filmmakers.

The EPA guidance publications on neurocognition in schizophrenia

A. Vita

Experimental and Clinical Sciences, University of Brescia, Brescia, Italy
doi: 10.1192/j.eurpsy.2025.209

Abstract: Introduction: Although cognitive impairment is a core symptom of schizophrenia related to poor outcome in different functional domains, it still remains a major therapeutic challenge. To date, cognition is still poorly assessed in both research and clinical settings and no comprehensive treatment guidelines for assessment and treatment of cognitive impairment in schizophrenia are implemented.
Objectives: The aim of the European Psychiatric Association (EPA) guidance paper was to provide a comprehensive meta-review of the current available evidence for the assessment of cognitive functions in schizophrenia both in research settings and in real-world clinical practice and for treatment of cognitive impairment, structured into three sections: pharmacological treatment, psychosocial interventions, and somatic treatments.
Results: Based on the reviewed evidence, the EPA guidance recommends a comprehensive and systematic assessment of neurocognitive and social cognitive domains in schizophrenia, in all phases of the disorder, as well as in subjects at risk to develop psychosis. It is recommended not only the use of observer reports, but also of self-reports and interview-based cognitive assessment tools. As for treatment, the EPA guidance recommends an appropriate pharmacological management as a fundamental starting point in the treatment of cognitive symptoms in schizophrenia. Among psychosocial interventions, cognitive remediation and physical exercise, and some variables have been confirmed as core elements for cognitive remediation effectiveness.

Conclusion: The dissemination of the EPA guidance papers may promote the development of shared guidelines concerning the assessment and treatment of cognitive functions in schizophrenia, with the purpose to improve the quality of care and to achieve clinical recovery in this population.

Negative symptoms and social cognition as mediators of the relationship between neurocognition and functional outcome in schizophrenia

A. Mucci* on behalf of ECNP Schizophrenia Network and ECNP Schizophrenia Network

Mental and Physical Health and Preventive Medicine, University of Campania L. Vanvitelli, Naples, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.210

Abstract: The presentation will summarize recent findings on the role of the two domains of negative symptoms (motivational impairment and expressive impairment) and social cognition as mediators of the impact of neurocognitive impairment on functional outcomes in people living with schizophrenia (PLWS).
One hundred and fifty subjects from 8 different European centers were recruited. Our data showed that the expressive impairment predicted global functioning and together with motivational impairment fully mediated the effects of neurocognition on the same outcome. Motivational impairment was a predictor of personal and social functioning and fully mediated neurocognitive impairment effects on the same outcome. Both motivational and neurocognitive impairments predicted socially useful activities, and the emotion recognition domain of social cognition partially mediated the impact of neurocognitive deficits on this outcome.
Our results indicate that pathways to functional outcomes are specific for different domains of real-life functioning and that negative symptoms and social cognition mediate the impact of neurocognitive impairment on different domains of functioning. Our results suggest that psychosocial interventions should target both negative symptoms and social cognition to enhance the functional impact of cognitive remediation.

Assessing CIAS in clinical routine

A. Erfurth[1,2*] and G. Sachs[2]

[1]1st Department of Psychiatry and Psychotherapeutic Medicine, Klinik Hietzing and [2]Medical University of Vienna, Vienna, Austria
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.211

Abstract: Cognitive impairment associated with schizophrenia (CIAS) is a relevant problem and can be well assessed in different ways, as described in an EPA guidance paper (1). In routine clinical practice, the clinician usually relies on targeted questions to elicit psychopathological findings, as described in the AMDP system (2), for example. If there is a need for a more precise assessment of cognitive dysfunction, also in a transdiagnostic way, the Screen for Cognitive Impairment in Psychiatry (SCIP) (3) has recently been used by several working groups.
In a recent pilot study (4), we used the German version of the SCIP (SCIP-G) (5,6) to assess cognitive impairment in acute psychiatric inpatients diagnosed with psychotic disorders, bipolar disorder and depression.

The role of add-on strategies (cognitive enhancers, cognitive remediation)

G. Sachs[1*] and A. Erfurth[1,2]

[1]Medical University of Vienna and [2]1st Department of Psychiatry and Psychotherapeutic Medicine, Klinik Hietzing, Vienna, Austria
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.212

Abstract: Cognitive impairments are present from the first manifestations of the disorder, including social cognition in individuals at ultra-high risk for psychosis (UHR). While advances in psychopharmacology in recent decades have significantly altered the course of the illness, antipsychotic therapy is more effective in treating positive symptoms than negative symptoms, comorbid depression, and cognitive and social cognitive dysfunction. Again, cognitive impairment has a significant impact on functional outcome, more so than symptom severity.

Due to the particular significance of cognitive deficits, it is very important to identify them accurately at an early stage. Strategies for identifying cognitive deficits are presented in an EPA guidance paper. To improve cognition in patients with schizophrenia, it has been suggested to combine pharmacotherapy with neuropsychological training. A meta-analysis showed the positive effect of cognitive remediation programmes in schizophrenia. While the strategies available today for the treatment of cognitive dysfunction are useful and should be implemented, it is hoped that pharmacological add-on strategies will come onto the market to have a greater effect on cognitive impairments.

Crisis Support VR: Bridging the Gap in Psychological First Aid Training -from initial idea to real virtual training

C. Hveem

Department of Preparedness and Security Protection, Sahlgrenska University Hosptial, Gothenburg, Sweden
doi: 10.1192/j.eurpsy.2025.214

Abstract: This presentation will explore the development and implementation of the Crisis Support VR project, funded by the VGR Innovation Fund and involving five hospitals and primary care. In today's society, the need for crisis support is more pressing than ever. However, we identified a significant gap in opportunities to practice Psychological First Aid. To address this, Region Västra Götaland collaborated with VirtualSpeech to create a system that has been tested by hospital staff, emergency services, and crisis support teams. This presentation will detail the project's journey from its inception to its current state, highlighting the challenges and successes encountered along the way.

Attitudes towards generative-AI based Virtual patient systems in crisis support training

S. K. Mårtensson

IHV, Institution of health science, Skövde, Sweden
doi: 10.1192/j.eurpsy.2025.216

Abstract: While generative AI (genAI) has made significant advances, millions of people are facing humanitarian crises, resulting in the denial of their basic human rights. One humanitarian response to addressing humanitarian crises is crisis support teams with knowledge of psychological first aid (PFA). In humanitarian crises, skilled practice in PFA by crisis support teams can strengthen the mental health of affected individuals, which can be crucial to ensuring societal well-being. At the same time, there are major challenges in training crisis support teams in PFA. With advancements in genAI, there are opportunities to develop virtual patient systems to enhance PFA training for crisis support teams. This presentation will share preliminary data collected through the genAI-agents survey, which explores technological openness, attitudes and learning through genAI and genAI-based virtual patient systems in healthcare education as well as specifically targeted questions to the genAI-based VP system Crisis Support-VR. This survey is a part of a larger project focusing a central research question Does Crisis Support-VR enhance the skills and ability of crisis support teams to deliver effective PFA, thereby strengthening the mental health of individuals affected by humanitarian crises with two interconnected sub-goals; • to empirically explore health and medical staff within children, youth and adult services learning in Crisis Support-VR, • to develop an educational module for training and practice opportunities in PFA to support and help national and international organizations train crisis support teams in applying PFA to children, youths an adults affected by humanitarian crises.

Open questions in ethics of virtual training

M. Lamb

Informatics, University of Skövde, Skövde, Sweden
doi: 10.1192/j.eurpsy.2025.218

Abstract: In recent years, developments in Generative artificial intelligence (genAI) have opened new possibilities for continuous education that were recently only science fiction. However, genAI introduces several ethical considerations and ethical issues continue to appear. These include privacy, ownership, accuracy, bias, psychological impact, and environmental impact. In this workshop we will consider where these ethical issues might specifically intersect with the development and implementation of genAI in training professional conversational skills in the context of professional mental health support. Understanding these ethical issues is important for ensuring positive and sustainable impact on society and individual health. As a part of this workshop, we consider theoretical issues, but we will also look at methods to ensure the development of ethical and trustworthy genAI systems, including transparency and human-in-the-loop methods, along with quality and risk management systems. Moreover, when considering worker health, it is will be important that future work empowers workers to continue to develop in their field, without introducing additional harms such as accessibility problems or exposure to harmful imagery or interactions.

Current situation in Europe: different prospective

I. Tarricone

University of Bologna, Bologna, Italy
doi: 10.1192/j.eurpsy.2025.219

Abstract: Introduction. Previous evidence showed significant discrepancies in psychiatric services utilization between migrants and reference populations in Europe. An important barrier for migrants to Europe is the lack of adequate legal entitlements. Sometimes these barriers are mistakenly attributed to cultural differences and misunderstandings because the term 'culture' may be used as a putative politically correct expression reifying social differences and neglecting discrimination. Our study aims were to evaluate incidence and characteristics of psychiatric hospitalizations of migrant patients compared with reference populations and to assess how the COVID-19 pandemic affected admissions. Methods. All patients admitted to the psychiatric ward "SPDC-Malpighi" of the Bologna Mental Health Department, Italy, from 01/01/2018 to 31/12/2020 were included. Differences in sociodemographic and clinical characteristics were tested by migrant status. Incidence rate ratios of hospital admissions by migrant status were estimated via Poisson regression considering population-at-risk, gender, and age-group. Results. Migrants had higher hospitalization rates due to any psychiatric disorder (IRR=1.16). The risk was especially pronounced among women (IRR=1.25) and within the youngest age-group (IRR=3.24). Young migrants had also a greater risk of compulsory admission (IRR=3.77). Regarding admissions due to a specific diagnosis, we found relevant differences in hospitalization rates for psychosis, mood disorders, and personality disorders. Finally, migrants were more likely to be admitted via the Emergency Department and less likely to be referred from a specialist. Discussion. During the year of pandemic (2020) we observed an increase in the proportion of migrants admitted voluntarily or compulsorily. Migrants, especially those from the youngest age-group, had higher hospitalization rates for any disorder. Younger migrants were also at higher risk of compulsory treatment. The distribution of psychiatric admissions during the pandemic period seemed to have further increased discrepancies in mental healthcare needs and provision between migrants and the reference population. Tailored interventions and policies are urgently needed to address this issue. Keywords Psychiatric admissions · Migrants · Pandemic · Compulsory treatments References: Tarricone I, D'Andrea G, Galatolo M, Carloni AL, Descovich C, Muratori R; Bo-East Psychiatric Admissions Study Group. Mental health disorders and the risk of abuse of prescribed opioids

G. Dom

University of Antwerp, Antwerp, Belgium
doi: 10.1192/j.eurpsy.2025.245

Abstract: Chronic (non-cancer) pain is a rising problem within Western population. Importantly, people with mental illness have disproportionally high levels of (chronic) pain. Prescription opioid medications are frequently initiated for the treatment of chronic pain. This, despite the growing evidence showing a lack of effectivity and an increased risk of complications such as the development of substance use disorders. Specifically, people with MH problems appear to be more vulnerable to lose control and develop opioid use disorders.

Intersecting paths: exploring the link between neurodevelopmental disorders and chronic pain

O. Kilic

Department of Neurosciences, Bezmialem Vakif University, Institute of Health Sciences, Istanbul, Türkiye
doi: 10.1192/j.eurpsy.2025.246

Abstract: Individuals with neurodevelopmental disorders, such as ADHD and autism spectrum disorder, often experience higher rates of chronic pain compared to the general population. Potential shared mechanisms could be central sensitization, muscular dysregulation and altered pain experiences. Individuals with ADHD and chronic pain frequently have a lower health-related quality of life, including higher pain interference and depressed symptoms. Psychological inflexibility, insomnia and hypermobility are identified as mediators in the relationship between neurodevelopmental symptoms and chronic pain. Understanding these connections can aid in developing targeted interventions to improve the quality of life for individuals with neurodevelopmental disorders experiencing chronic pain.

Psychiatric management of fibromyalgia

A. J. Krupa

Department of Affective Disorders, Jagiellonian University Medical College, Cracow, Poland
doi: 10.1192/j.eurpsy.2025.247

Abstract: Fibromyalgia is not a primarily psychogenic disorder, however due to high levels of comorbidity with psychiatric disorders and shared therapeutic targets, psychiatrists can play an important role in the diagnosis and treatment of fibromyalgia.
Fibromyalgia is a chronic pain syndrome affecting around 2-5% of the general population. Fibromyalgia's core symptom is the persistent generalized pain, its other symptoms include fatigue, stiffness, depressed mood, anxiety and sleep disturbance. Although some psychiatric symptoms are an integral part of fibromyalgia clinical presentation, in a significant part of patients their severity warrants a specific psychiatric diagnosis and management. Available data shows high rates of psychiatric comorbidity in fibromyalgia, with lifetime prevalence reaching 9-33% for anxiety disorders, 16% for post traumatic stress disorder, 63% for depression, 26% for bipolar disorders. Psychiatric comorbidity in fibromyalgia is associated with the severity of fibromyalgia, its impact on

© The Author(s), 2025. Published by Cambridge University Press on behalf of European Psychiatric Association. EUROPEAN PSYCHIATRIC ASSOCIATION

patients functioning, quality of life and socioeconomic status. Moreover, the works of our team have also shown that some psychopathological symptoms such as depression, anxiety, anhedonia, chronobiological preferences and circadian rhythm disruptions as well as some psychological traits are linked to lack of response to pharmacological treatment in fibromyalgia.
The current knowledge on fibromyalgia etiopathogenesis is incomplete and does not warrant a comprehensive description. There are no biomarkers or objective tests, which would verify the fibromyalgia diagnosis, which is therefore based primarily on the physician's history-taking and fulfillment of criteria. In effect, the group of patients diagnosed with fibromyalgia is most likely heterogeneous, regarding the biological basis of its symptoms, clinical presentation and susceptibility to treatment. This also means treatment is symptomatic and characterized by limited effects.
Fibromyalgia management requires a multidisciplinary approach, with emphasis on non-pharmacological interventions such as physical activity, cognitive–behavioral/mindfulness psychotherapy, physical therapies. For a large number of fibromyalgia patients these interventions are not sufficiently effective and there is a need for pharmacotherapy. The use of selective serotonin and noradrenaline reuptake inhibitors (SNRI) and pregabalin, which are commonly used to manage depression and anxiety, is supported by best scientific evidence. Also other drugs used for psychiatric disorders such as amitriptyline, gabapentin, quetiapine or naltrexone (in low doses) were proven useful in fibromyalgia management.
This presentation will sum up current knowledge on psychiatric comorbidity in fibromyalgia and treatments which psychiatrists can offer to fibromyalgia patients.

Optimizing Psychopharmacotherapy in Special Populations: Educating Language Models for Tailored Treatment Approaches

G. Vannini

Swiss Timing Ltd, Corgemont, Switzerland
doi: 10.1192/j.eurpsy.2025.248

Abstract: In recent years, artificial intelligence has increasingly demonstrated its potential to transform healthcare, particularly in the domain of psychopharmacotherapy. This workshop explores the integration of language models into the personalization of treatment strategies for special populations, including those with complex comorbidities or unique pharmacokinetic profiles. By educating language models with domain-specific data, we can enhance their capacity to support clinicians in decision-making processes, optimize treatment outcomes, and reduce the risk of adverse drug reactions. Attendees will gain insights into the methodologies for training AI models on tailored datasets, addressing challenges in bias mitigation and ethical considerations, and leveraging these tools for real-world clinical applications. This session aims to foster a deeper understanding of how cutting-edge AI can reshape psychopharmacological practices and empower clinicians with data-driven insights.

Psychopharmacological treatment in elderly patients

M. Siwek

Department of Affective Disorders, Jagiellonian University Medical College, Krakow, Poland
doi: 10.1192/j.eurpsy.2025.249

Abstract: Mental disorders in the elderly occur much more often than in young adults, and their prevalence increases significantly with age and in the case of people receiving institutional care. Psychopharmacotherapy in an elderly patient is much more challenging and requires more restrictive safety strategies than in younger patients. The significantly increased risk of interactions, side effects and complications resulting from: comorbidities, systemic changes due to aging and, as well as their pharmacotherapy, are a serious problem in the treatment of elderly patients. It should be emphasized that the safety profile may be different in the elderly compared to the young adults - some complications that are rare in younger patients, e.g. bleeding complications, fractures and bone loss, cataract progression, hyponatremia, falls, QT prolongation, stroke, pneumonia and others, are a much more common problem among seniors and their risk should be considered at the initial stage of pharmacotherapy selection. In the case of some drugs (e.g. antipsychotics), the accumulation of serious complications may significantly increase the risk of premature mortality, if they are used incorrectly. Moreover, it should be remembered that certain side effects, e.g. orthostatic hypotension, may occur with drugs for which these side effects are unlikely in younger patients. During the treatment process, it is also necessary to monitor the presence and severity of side effects, such as: constipation, dry mouth, tremors, urination problems, excessive sleepiness or cognitive impairment, which may reduce the quality of life, particularly in an elderly patient. This presentation will provide a brief and practical clinical guide to safe and effective pharmacotherapy in the elderly patients.

Mental health treatment for people with dual diagnosis

L. Lien

Health and welfare, University of Inlandet, Elverum, Norway
doi: 10.1192/j.eurpsy.2025.250

Abstract: In this presentation I will show that mental health treatment for people with dual diagnosis is not very different from treatment of mental disorders without addiction problems. There are a few points that will be raised like interactions with the drug of choice for the patients and the problem arising from compliance.
The most important point that will be presented is the fact that too many people with dual disorders go untreated. There is a need to rise awareness of this problem within our profession.
The main aim of treatment is often to replace some of the effects that the patients experience using drugs like depression, irritability, fluctuating thoughts and sleep problems.

A revised biopsychosocial model for explaining complexity to mental disorders

A. Fiorillo

University of Campania "Luigi Vanvitelli", Naples, Italy
doi: 10.1192/j.eurpsy.2025.251

Abstract: The biopsychosocial model was first conceptualized by George L. Engel in 1977 in order to explain the contribution of biological, social and psychological factors in determining mental (and physical) illnesses. This model gained new attention in recent years: while many authors consider it as a complete framework, others highlight its clinical, scientific and theoretic vagueness. A revised biopsychosocial model is being proposed, including causal interactions within and between biological, social and psychological factors as the benchmarks of the complexity of mental disorders.

Are neuroinflammation and citokines possible novel targets for therapeutic treatments?

P. Falkai

Psychiatry, Munich University Hospital, Munich, Germany
doi: 10.1192/j.eurpsy.2025.252

Abstract: Schizophrenia is a serious mental illness with positive, negative and cognitive dysfunctions and a significant deterioration in psychosocial functioning. Interactions between genetic predisposition and environmental stressors at the early stages of life, and subsequently a molecular level neurodegeneration process are important in the development of schizophrenia. Current approaches suggest that cytokines-induced neuroinflammation might have a role in the development of several psychiatric disorders, including schizophrenia.

The exposome paradigm for severe mental disorders: is it useful for clinical practice?

S. Guloksuz[1,2]

[1]Psychiatry, Maastricht University Medical Center, Maastricht, Netherlands and [2]Psychiatry, Yale School of Medicine, New Haven, United States
doi: 10.1192/j.eurpsy.2025.253

Abstract: In this presentation, I will explore how the exposome paradigm can be leveraged to advance clinical practice in psychiatry. Specifically, I will highlight the potential of cumulative environmental risk scores to predict outcomes in severe mental disorders, such as the exposome score for schizophrenia (ES-SCZ). Numerous socio-environmental factors have been linked to mental disorders, including childhood adversities, stressful life events, substance use, obstetric complications during pregnancy and childbirth, and urban living. Environmental factors do not exist in isolation; they form complex networks of interrelated and interactive elements. In this regard, the exposome represents the totality of an individual's environmental exposures throughout their lifetime. The exposome framework introduces a holistic approach to embrace this complexity and a theoretical framework to investigate the poly-gene and poly-environment etiology of psychiatric disorders.
Guided by the exposome framework, we have recently estimated the ES-SCZ, a cumulative environmental exposure score for schizophrenia, including cannabis use, winter-birth, hearing impairment, bullying, and five domains of childhood adversities (emotional and physical neglect, along with emotional, sexual, and physical abuse). The ES-SCZ successfully differentiated individuals with schizophrenia, accounting for 28% of the variance in an independent case-control sample. Subsequently, we have tested the risk stratification properties and the predictive performance of the exposome score for schizophrenia in the general population. The ES-SCZ had strong discriminative performance for schizophrenia (AUC = 0.84) and was associated with the degree of psychosis risk in the general population. Finally, we tested the performance of ES-SCZ for dissecting the functional and symptomatic outcome heterogeneity in patients with psychosis in four different cohorts (EUGEI, GROUP, Athens FEP, and HAMLETT-OPHELIA). ES-SCZ was associated with poor overall functioning and cognitive impairment at baseline and follow-up visits. ES-SCZ was also temporally associated with poor symptomatic improvement from baseline to follow-up assessments, particularly the negative symptom dimension. Furthermore, models that included the polygenic risk score for schizophrenia and clinical features showed that the relationship between ES-SCZ and functional outcomes cannot be explained by genetic or clinical risk factors alone.
Overall, our findings demonstrate the potential benefits of the exposome score for schizophrenia, which can be integrated for early detection, outcome prognostication, clinical staging, and risk stratification in the future.

Should cannabis be legalised?

R. Keet

FIT-academy, GGZ Noord-Holland-Noord, Heerhugowaard, Netherlands
doi: 10.1192/j.eurpsy.2025.254

Abstract: Legalizing cannabis can yield significant benefits for public mental health by fostering harm reduction, promoting medical access, and mitigating societal stigma. While concerns about misuse exist, a well-regulated cannabis policy can outweigh these risks and provide a balanced approach to mental health promotion.
1. Harm Reduction through Regulation Prohibition often drives cannabis use into unregulated markets, where the lack of quality control increases risks of contamination with harmful substances. Legalization allows governments to regulate cannabis production, ensuring product safety and controlled potency. This can reduce

incidents of adverse reactions, particularly those exacerbated by high-potency strains or toxic additives. A regulated market also discourages illicit activity, reducing exposure to dangerous drugs often sold alongside cannabis in black markets. 2. Promoting Medical Access and Mental Health Treatment Legalization enhances access to cannabis for therapeutic purposes, particularly for mental health conditions such as chronic pain and opens the door to explore the potential benefor for patents with anxiety and post-traumatic stress disorder (PTSD), and. Studies indicate that cannabinoids can alleviate symptoms of stress and anxiety when used responsibly and under medical supervision. By integrating cannabis into healthcare systems, individuals struggling with mental health disorders can benefit from a natural and potentially less addictive alternative to pharmaceuticals like opioids or benzodiazepines, which carry significant risks of dependency. 3. Addressing Stigma and Encouraging Open Dialogue Legalization reduces societal stigma associated with cannabis use, enabling more individuals to openly discuss their experiences and seek help for misuse if needed. Public health campaigns can then focus on education about responsible use, mental health implications, and support systems. Decriminalizing cannabis also reduces the disproportionate criminalization of marginalized groups, fostering a more inclusive and equitable approach to public health. 4. Potential to Reduce Alcohol and Opioid Use Research has suggested that legal cannabis availability is associated with reductions in alcohol and opioid consumption, substances that are more harmful to both physical and mental health. By providing a less harmful alternative for relaxation or pain management, cannabis legalization could mitigate the societal burden of these substances, including addiction and overdose crises. Conclusion While cannabis legalization requires careful regulation to mitigate risks like overuse or dependence, its potential benefits for public mental health are substantial. By reducing harm, enhancing medical access, and promoting a more informed and equitable societal approach, legalization represents a forward-thinking public health policy that prioritizes well-being over punitive enforcement.

Does Cannabis Legalization Contribute to an Increase in the Incidence and Prevalence of Psychotic Disorders?

D. Quattrone

Social, Genetic, and Developmental Psychiatry Centre - Institute of Psychiatry, Psychoolgy and Neuroscience, King's College London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.255

Abstract: Cannabis legalisation has undergone a rapid global transformation, with varying policy approaches and public health implications across different geographic areas and social contexts. Several arguments have been proposed to support cannabis legalisation, ranging from control of the quality and potency of the market products, harm reduction, addressing the black market activities, reducing crime, and economic benefit. However, cannabis use has been associated with public health concerns, and it has been established as the most preventable risk factor for psychotic disorders.

This work aims to dissect the key arguments supporting cannabis legalisation through the following objectives: 1) reviewing the relationship between cannabis legalisation and the incidence and prevalence of psychotic disorders in countries where cannabis has been legalised, as well as changes in incidence rates over time in those countries where legalization is currently under debate; 2) examining the relationship between cannabis use and psychopathological outcomes using a syndemic approach; and 3) presenting original data from the epidemiological branch of the EC-1 study, aiming to identify risk factors for psychopathology, violence, and aggression in South London.

Marrying up new trends in clinical research: AI and -omics

D. Cavaleri

School of Medicine and Surgery, University of Milano-Bicocca, Monza, Italy
doi: 10.1192/j.eurpsy.2025.256

Abstract: Artificial intelligence (AI) and -omics techniques (genomics, proteomics, metabolomics) represent two rapidly evolving fields that are increasingly intersecting to transform clinical research and healthcare.

AI, aiming to mimic human intelligence through computational modelling, possesses extraordinary capabilities for big data analysis. -Omics, offering quantifiable and dynamic readouts of the molecular state of the subject, can generate large databases covering hundreds to thousands of molecules with complex relationships.

Combining AI-driven insights with the wealth of data generated by genomics, transcriptomics, proteomics, and metabolomics can help uncovering complex biological networks, with the potential to revolutionize our understanding of disease mechanisms, improve patient stratification, and optimize therapeutic interventions.

In this presentation, the concepts of AI and -omics and their combined application to clinical research will be discussed, summarizing the strengths and limitations of these approaches. Studies leveraging AI across various -omics domains will be presented. Key advances, ongoing challenges, and future perspectives in this rapidly evolving field will be debated.

While still in the early stages, the synergistic partnership between metabolomics and AI represents an exciting frontier that holds great promises for groundbreaking advancements in clinical research and human health, paving the way toward a new era of precision medicine.

Speech analysis in psychiatric disorders: experiences from the CALIBER study

G. Anmella

Bipolar and Depressive Disorders Unit, Hospital Clinic of Barcelona, Barcelona, Spain
doi: 10.1192/j.eurpsy.2025.257

Abstract: Bipolar disorder (BD) is characterized by mood and cognitive fluctuations that manifest in speech patterns. Current assessments rely on subjective clinical evaluation, but advances in natural language processing (NLP) offer new opportunities for objective monitoring. This study analyzes speech from BD patients across different mood states—euthymia, mania, and depression—using structured tasks, spontaneous speech, and standardized text reading. Key acoustic, linguistic, and emotional features are extracted and correlated with clinical scales. Machine learning models are being developed to predict symptom severity and mood phase. This approach could provide reliable digital biomarkers, enhancing diagnosis, monitoring, and early relapse detection in BD. Standardized speech protocols may pave the way for international collaboration and large-scale validation.

Burnout and mental health issues in the psychiatry training and career pathway

E. Chumakov

Department of Psychiatry and Addiction, St Petersburg State University, St Petersburg, Russian Federation
doi: 10.1192/j.eurpsy.2025.258

Abstract: Burnout and mental health issues have become increasingly prevalent among psychiatry trainees and early career psychiatrists, posing significant challenges to their well-being. This presentation explores the multifaceted relationship between psychiatry training environment and the occurrence of burnout, characterized by emotional exhaustion, depersonalization, and a diminished sense of personal accomplishment. Factors contributing to the severe burnout in psychiatry trainees include long working hours, lack of supervision, and not having regular time to rest (Jovanović N. et al., 2016). Other potential factors described include the high demands of clinical responsibilities, emotional strain from patient interactions, and inadequate support systems. Encountering possible suicidal patients and coping with patients' violence are other factors that can have a strong influence on psychiatry trainees and early career psychiatrists' clinical activity, especially in the absence of appropriate training in the field and supervision (Chumakov E. et al., 2022; Longo G. et al., 2023). Studies indicate that a significant proportion of psychiatry residents experience symptoms of mental distress (Pitanupong J. et al., 2024; Toni F. et al., 2024) with depression being an important source of impaired mental well-being. Furthermore, the stigma surrounding mental health within the medical community often discourages trainees from seeking help, exacerbating feelings of isolation and distress. There's no question that poor mental health can affect not only psychiatry trainees and early career psychiatrists' personal health but also their professional development and patient outcomes. In this presentation the implications of these issues for the psychiatry field will be discussed. There's a growing demand for advocacy for comprehensive training programs that integrate wellness strategies, enhance supervision, and promote open conversations about mental health. By fostering a supportive environment and prioritizing self-care, the psychiatry community can mitigate the risks of burnout and mental disorders among peers, ultimately leading to a more resilient workforce and improved patient care. This presentation underscores the need to support the mental health of future psychiatrists and ensure the integrity of mental health services.

Burnout in doctors

D. Bhugra

Centre for Affective Disorders, Kings College London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.259

Abstract: Burnout is a set of experiences and symptoms which occurred in the context of stress and high ideals in the helping professions who feel drained, exhausted, tired, listless and unable to cope. Burnout leads to disengagement, blunted emotions, helplessness and hopelessness with feeling trapped causing detachment and depression. Prevention of burnout is important and includes interventions at policy, institutional and personal levels. These resources must include financial and human resources where appropriate; prompt and culturally acceptable help is available and easily accessible. Institutions must allocate sufficient funds for well-being of its staff. Various steps can be taken but perhaps most important is accessibility of services in a non-stigmatising manner. These services must be confidential, fit for purpose and widely advertised and accessible. Physical space to rest and access to affordable nutritious food are important. Access to occupational heath services or primary care are important.

Prevention strategies in stress coping and life crisis in trainees and early career psychiatrists

D. Gurrea Salas* and ECP Task Force on Communication and Publications

Department of Addictive Disorders, Psychiatric Services Aargau (PDAG), Brugg, Switzerland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.260

Abstract: The current post-covid situation and the increase of violent situations in the ward within another risk factors flourished

within the last years. With this input is aimed, the change of culture into the active implementation of stress and therefore mental health prevention strategies in the workplace and in safe spaces after the shift. Coping Strategies have to be implemented to improve the resilience and the ability to act (empowerment) in the early career stages of trainees and early career psychiatrists, as they are at risk of life crises and suicidal behaviors.

Wellbeing as antidote against burnout: interventions and actions

L. Cuffaro[1,2] on behalf of European Academy of Neurology Wellbeing Task Force (EAN-WTF)

[1]Neurology Department & Brain Health Service, University of Milan Bicocca, Monza and [2]Candido Neuro Care Institute, Agrigento, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.261

Abstract: Background: Burnout among mental health professionals poses a significant threat to personal wellbeing, patient care, and healthcare systems. Addressing this challenge aligns with the broader mission of the European Academy of Neurology (EAN) to promote brain health not only for patients but also for clinicians. This presentation highlights education, collaboration, and systemic interventions, integrating neurological and psychiatric perspectives.
Methods: This initiative stems from the EAN Task Force for Wellbeing (TFW), in collaboration with the European Psychiatric Association (EPA). A multipronged strategy was designed to enhance awareness, build resilience, and foster systemic reforms:

- Educational Media: A podcast series exploring burnout's conceptualization, its neurobiological and psychological aspects, gender disparities, and practical solutions.
- Interactive Webinars: Interdisciplinary sessions combining insights from neurology and psychiatry, showcasing evidence-based strategies and technological innovations.
- Public Debates: Open forums to engage professionals across career stages, raising awareness and encouraging action to tackle burnout.

These initiatives were supplemented by systematic reviews, case studies, and suggestions of novel tools to monitor mental health and stress factors.
Results: The combined educational and intervention efforts yielded significant outcomes:

- Advancing Brain Health for Clinicians: Awareness initiatives emphasized the vital link between clinician brain health and professional resilience
- Skill Development and Resilience: Practical strategies for time management, mentorship, and self-care were disseminated through case studies and interactive discussions.
- Collaborative Solutions: Webinars and public debates highlighted shared challenges and fostered interdisciplinary advocacy for systemic reform.

Discussion: Burnout is not just an individual issue but a systemic challenge requiring collective action. By prioritizing clinician brain health as a mission, the EAN and EPA collaboration provides a unifying framework to tackle burnout. Educational initiatives bridged the gap between theory and practice, while public debates fostered community engagement and systemic advocacy. Interdisciplinary collaboration underscored the shared nature of burnout and the need for unified, brain-health-centric strategies.
Conclusion: Promoting wellbeing through education, collaboration, and innovative tools aligns with the broader goal of achieving brain health for clinicians. These initiatives provide a sustainable pathway to counteract burnout and foster a resilient and thriving workforce. Continued investment in education, public discourse, and systemic reform is essential to realizing this mission.

ECP018

Global advances and challenges in perinatal psychiatry

N. Jovanovic

Queen Mary, University of London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.262

Abstract: Perinatal psychiatry is a rapidly evolving subspecialty focused on diagnosing, recognising early, and treating mental disorders in pregnant and postpartum individuals, up to two years after childbirth (timeframes vary globally). The field has gained attention as governments around the world work to meet the United Nations Sustainable Development Goals (SDGs), particularly SDG 3 (health and well-being) and SDG 5 (gender equality), aiming to improve maternal, infant, and child health outcomes.
In most countries, perinatal mental illness is managed by family doctors, midwives, and general adult psychiatrists, although some countries have developed specialist community and inpatient perinatal mental health services. The goal is effective treatment to improve pregnancy outcomes, parental mental health, social functioning, and child development. Studies show that infants of mothers with untreated perinatal depression and psychosis are at higher risk of long-term mental health disorders and poor social and educational outcomes. Early detection and efffective and acceptable interventions are key to breaking this cycle.
This presentation will address global advances and ongoing challenges. Significant progress includes increased awareness, emerging specialist services, novel pharmacological treatments with improved safety profiles, expanded evidence-based psychosocial interventions, and a focus on maternal suicide prevention, a key driver of maternal mortality. However, major challenges remain: perinatal suicide is a leading cause of maternal death, poor quality of evidence for prescribing in pregnancy and lactation, long-term morbidity due to untreated mental illness is often overlooked, and access to care is limited especially in low- and middle-income countries. Social stigma and structural barriers also prevent many from seeking help. Addressing these issues requires a global, multidisciplinary approach, integrating public health initiatives, policy changes, workforce training, and research innovations to ensure equitable access to high-quality perinatal mental health care worldwide.

Diagnostics and treatment of female ADHD in the perinatal period

A. Todzia-Kornaś

Military Institute of Medicine, Warsaw, Poland
doi: 10.1192/j.eurpsy.2025.263

Abstract: Pregnancy-related hormonal fluctuations, such as changes in estrogen and progesterone, can exacerbate ADHD symptoms, complicating the diagnostic process. Overlap with symptoms of pregnancy-related conditions, such as fatigue and mood instability, further obscures ADHD identification.
Non-pharmacological interventions, including cognitive-behavioral therapy (CBT) and psychoeducation, are first-line recommendations. For patients requiring pharmacological treatment, stimulant and non-stimulant medications must be considered cautiously, weighing risks such as low birth weight or preterm labor against the potential impact of untreated ADHD on maternal functioning. Emerging data suggest that atomoxetine and certain stimulants may be relatively safe under close monitoring.
Untreated ADHD in pregnant women is associated with higher risks of prenatal stress, inadequate prenatal care, and postpartum depression, highlighting the need for tailored management strategies.
Keywords: ADHD, pregnancy, diagnosis, treatment, pharmacological safety, maternal mental health.

Mastering Therapeutic Drug Monitoring: Essential Strategies for Pregnancy and Breastfeeding

G. Schoretsanitis

Department of Psychiatry, Psychotherapy and Psychosomatics, Hospital of Psychiatry, Zurich, Switzerland
doi: 10.1192/j.eurpsy.2025.264

Abstract: Measuring medication levels in blood and/or milk of psychotropic-treated women during pregnancy and lactation provides significant benefits for optimizing maternal mental health while minimizing risks to the developing fetus or breastfeeding infant. This approach supports individualized treatment plans by addressing the unique pharmacokinetic and pharmacodynamic changes that occur during these physiological states. Among key benefits monitoring blood levels ensures that psychotropic medications remain within therapeutic ranges, thereby reducing the likelihood of relapse while avoiding toxicity. Moreover, measuring drug levels aids in balancing maternal benefits against fetal risks by enabling dose adjustments to minimize unnecessary fetal exposure while maintaining efficacy. It is particularly relevant for medications with narrow therapeutic indices or significant placental transfer. Additionally, pregnancy induces changes in drug absorption, distribution, metabolism, and excretion, which can lead to subtherapeutic levels. Monitoring essentially helps clinicians anticipate and adjust for these alterations, ensuring consistent drug efficacy. Further, postpartum, measuring drug levels in maternal blood and, when appropriate, in breastmilk provides data on infant exposure risks. This information is crucial for determining the safety of breastfeeding while continuing psychotropic therapy.
Last, drug level data allow clinicians to assess adherence, which is a major aspect during pregnancy and lactation.
Incorporating medication level assessments into risk management frameworks during pregnancy and lactation ensures that women receive evidence-based, safe, and effective psychotropic treatment while supporting fetal and neonatal well-being.

How to do research and be a researcher

R. Stewart

King's College London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.265

Abstract: There's a lot of advice and written material available on research methods but much less on 'how to be a researcher'. However, understanding this is as much a part of carrying out research as understanding a particular methodology. Having delivered countless teaching sessions on research design, I thought it would be interesting to consider (and attempt to write about) the origins of research principles, how these have developed over time, and what's common across different fields. As well as this, there are the more mundane realities of attracting funding and publishing output, and the common challenges of achieving career progression and success in complicated political structures. There are great opportunities in research, and few careers that are as continuously interesting and engaging, but it's wise to keep as clear a perspective as possible of the road behind and ahead.

Nine rules to follow in collaborative research

N. Sartorius

Association for the Improvement of Mental Health Programs, Geneva, Switzerland
doi: 10.1192/j.eurpsy.2025.266

Abstract: Introduction: After the exploration of factors relevant to the conduct of collaborative research it is possible to formulate a set of rules which vastly increase the probability of success in the study conducted collaboratively.
Methods: A systematic exploration of the manners in which collaborative research has been organized and of the relation between the method or organization and the successful completion of the study.
Objectives: The goal of this exploration was to formulate a set of rules which should be followed in conducting multicenter collaborative research to enhance the probability of its success.

Results: The examination of the experience in the conduct of the studies organized and lead by the author it was possible to formulate certain rules which, when followed, not only led to a successful completion of the studies but also led to a number of additional benefits for the centres in which the study was conducted. The nine principal rules which were formulated in this way will be presented.
Conclusions: Collaborative research is more likely to have useful results if it is developed bearing certain rules in mind.

ADHD in adulthood: Why should we not give up on getting the diagnosis right

J. S. Kooij[1,2]

[1]Psychiatry, Amsterdam UMC/VUMc, Amsterdam and [2]Adult ADHD, PsyQ, the Hague, Netherlands
doi: 10.1192/j.eurpsy.2025.267

Abstract: ADHD in adulthood is still an orphan diagnosis in many countries in Europe. This is due to lack of knowledge in the education of psychiatrists in adult psychiatry about the research findings on adult ADHD of the past 30 years. Why is this important?
ADHD is prevalent in about 3-5% of adults in the general population, but in at least 20% of patients in psychiatry, whether anxiety, depression, bipolar disorder, substance abuse disorders and many more. In adults with borderline personality disorder, ADHD symptoms in childhood precede the development of this personality disorder later in life even in the majority of cases. Not recognising and treating ADHD in adulthood means that this condition impacts the treatment outcomes of any other psychiatric comorbidity due to impairing inattention, impulsivity and hyperactive behaviour. Psychotherapy for instance is hard to comply to when ADHD is not treated first. Also compliance to medication often fails in case of untreated ADHD, leading to high relapse rates. Also the treatment of physical diseases for instance for astma, obesity and diabetes may fail in case of untreated ADHD. In fact, not treating ADHD may lead to chronicity of any other comorbid condition; one of the reasons that ADHD can be found in chronic therapy-resistent patients.
ADHD is comorbid with 34 of 35 investigated disorders and diseases in a Swedish registry study, of which many have in part a genetic background. Allergies, astma, migraine, irritable bowel syndrome, hypermobility and weak connective tissue seem to play a role in many of these diseases. Psychiatric comorbidities are also broad: anxiety, depression, bipolar disorder, autism, sleep disorders, substance abuse disorders, personality disorders, severe hormonal moodchanges across the lifespan in women, and PSTD. This summary points to the systemic nature of ADHD across the lifespan, that urgently needs more research and understanding.
The good news is that ADHD is a well treatable condition in about 80% of patients using psycho-education, stimulant and other medication, CBT and other psychotherapies. Comorbid conditions must be diagnosed and treated as well, and often first. Treatment offers stability for patients who have never experienced this from childhood. As such, the diagnosis of ADHD in adults is often a game changer, enabling patients for the first time to persevere to a better lifestyle, to prevent further damage due to sleep loss, substance abuse and obesity.
Training about diagnostic assessment and treatment is available via books, (online) training and webinars.
In this presentation, all resources will be discussed followed by Q and A.

Overlap between personality disorders and neurodevelopmental conditions

J. D. King

Division of Psychiatry, Imperial College London, London, United Kingdom
doi: 10.1192/j.eurpsy.2025.268

Abstract: We all have a personality, whether or not we also have a mental health disorder, and for some people parts of our personality lead to problems with others, or in getting on in our lives. Indeed the same might be said of neurodevelopmental conditions, autism, intellectual disability, ADHD, of which we understand there to be a spectrum of degree, and which in unfavourable circumstances produces difficulty and dysfunction. The combination of personality and neurodevelopmental pathology is common, so too is misdiagnosis between them. This talk will describe the key theories to understand the overlap, tackle diagnostic uncertainty, and outlines the ways in which support can be offered for the combination of the two.

Dissecting the Phenomenon of Suicidality in Patients with Obsessive-Compulsive Disorder: A Descriptive Psychopathological Study

Y. A. Ferrao[1,2], J. V. Bueno Ferrão[3]*, J. R. da Silva[1] and T. Yamaguchi[4]

[1]Psychiatry, UFCSPA; [2]Psychiatry, HMIPV; [3]Medicine, PUCRS and [4]Medicine, UFCSPA, Porto Alegre, Brazil

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.270

Introduction: There are conflicting and inconclusive results regarding suicidality in patients with obsessive-compulsive disorder (OCD).

Objectives: To describe the different psychopathological aspects of suicidality (suicidal ideation, suicide attempts, completed suicide, family history, etc.) in OCD.

Methods: In this case-control study we compared 114 patients with OCD and 127 controls (no OCD general hospital inpatients). The psychopathological aspects of suicidality were obtained through a 24 questions specific suicidality inventory (DETEC-S). Other instruments/data (Beck Depression and Anxiety Inventories, family history of psychiatric disorders, symptom severity scale, and psychiatric comorbidities) will be described in another study.

Results: Patients with OCD reported: less will to live (p=0.005); greater will to die (p<0.001); more reasons to die (p=0.022); greater lifetime history of suicidal ideation (SI) (p<0.001); accept the idea of dying (p<0.001); admit death as an escape from problems (p<0.001); suicidal plan in the past (p=0.019); admit courage and ability to commit suicide (p=0.003); no organization for the afterlife (p=0.021); have already talked to other people about SI (p<0.001); access to a lethal method (p=0.047); higher rates of family members, close people or friends who have already attempted suicide (p=0.008). They did not differ from the controls: would save themselves in case of an accident; current intention to commit suicide; able to control suicidal desire; would not commit suicide because of family, friends or religion; absence of current suicidal plan; suicidal desire or plan in the near future; writing a suicide note; prevalence of lifetime suicide attemp (SA); when they had SA, there was no need for medical care; and suicide success rates of family members, close people or friends. There was no significant difference in the total DETECT-S score (p=0.086). There was a moderate and direct correlation of suicidality scores with: the current severity of OCD and (r=0.32; p=0.001), especially at the expense of the severity of compulsions (r=0.35; p<0.001); and with the severity of depressive symptoms (r=0.43; p<0.001); average rate of lifetime improvement of symptoms (r=0.36; p=0.007). We found a moderate and indirect correlation with total quality of life scores (r=-0.47; p<0.001), especially at the expense of aspects related to the physical (r=-0.47), psychological (-0.47) and environmental (r=-0.42) domains (all with p<0.001).

Conclusions: Suicidality appears to be markedly present in patients with OCD (of the 24 psychopathological aspects of the DETECT-S questionnaire, patients had higher scores in 13 items) even when compared to patients admitted to a general hospital. A detailed approach to suicidality in patients with OCD may help in therapeutic planning and reduce patient suffering.

Anxiety and Mood Disorders on the Rise: Exploring Clinical Profiles and Risk Factors in the Netherlands

A. Gkitakou[1,2*], M. Ten Have[2], N. M. Batelaan[1], A. Luik[2,3] and B. W. Penninx[1]

[1]Department of Psychiatry, Amsterdam UMC, Vrije Universiteit Amsterdam, Amsterdam Public Health Research Institute, Amsterdam; [2]Trimbos Institute, Netherlands Institute of Mental Health and Addiction, Utrecht and [3]Department of Epidemiology, Erasmus MC University Medical Center Rotterdam, Rotterdam, Netherlands

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.271

Introduction: While an increase in mental disorders has been suggested, the role of societal changes, such as sociodemographic, vulnerability, or health-lifestyle factors, on this increase is scarce. This information is however crucial for health care policy and planning.

Objectives: We examined trends in the 12-month prevalence of anxiety and mood disorders, their clinical profiles, and how sociodemographic, vulnerability, and health-lifestyle risk factors may have contributed to these trends.

Methods: We used data from 11,615 respondents (mean age= 43.5, 53.5% female) of the Netherlands Mental Health Survey and Incidence Study, examining the general population in 2007-2009 (NEMESIS-2, n= 6,646) and 2019-2021 (NEMESIS-3, n= 4,969). The Composite International Diagnostic Interview 3.0 was used to determine DSM-IV diagnoses. Logistic regression and interaction analyses were then conducted to assess the association between risk factors and the prevalence of anxiety and mood disorders, while also evaluating changes over time between the two cohorts.

Results: The 12-month prevalence of all types of anxiety and mood disorders significantly increased from 2007–2009 to 2019–2022, with increases ranging from 56% to 125%. Clinical profiles of those with disorders were not milder in 2019-2022; there was greater mental health care use, a higher number of disorders, and an earlier age of onset. There was no consistent evidence that sociodemographic, vulnerability, or health-lifestyle risk factors became more prevalent over time or had a greater relative impact over time.

Conclusions: Our study showed a consistent increase in 12-month prevalence across all anxiety and mood disorders over the past decade. This rise in prevalence could not be explained by an increase in the absolute or relative impact of specific risk factors, nor were there significant differences in clinical profiles over time.

The Relationship between Kynurenine Metabolites and Executive Functions in Patients with Generalized Anxiety Disorder

D. F. Göy[1*], F. Kulacaoglu Ozturk[1], A. Unlu[2], H. Eroglu Icli[3] and M. A. Bik[2]

[1]Department of Psychiatry, Health Sciences University Prof. Dr. Mazhar Osman Bakirkoy Research and Training Hospital for Psychiatry and Neurological Diseases, Istanbul; [2]Department of Biochemistry, Selcuk University, Konya and [3]Department of Biochemistry, Health Sciences University Prof. Dr. Mazhar Osman Bakirkoy Research and Training Hospital for Psychiatry and Neurological Diseases, Istanbul, Türkiye

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.272

Introduction: Generalized anxiety disorder (GAD) is a common psychiatric condition characterized by excessive worry, concentration issues, and insomnia. Despite numerous studies, its neurometabolic mechanisms remain unclear.

Objectives: This study aims to compare the levels of kynurenine pathway metabolites between GAD patients and healthy control groups, and to investigate the relationship between kynurenine metabolism products, executive functions, and disease severity in GAD patients.

Methods: The study included 41 GAD patients and 41 healthy controls. Participants were enrolled after ruling out major depressive disorder using the Beck Depression Inventory. They then completed the Sociodemographic and Clinical Data Form, the Wisconsin Card Sorting Test (WCST), the Trail Making Test (TMT) A and B, the Digit Span Test (DST), the Verbal Fluency Test (VFT), the Stroop Test, and the State-Trait Anxiety Inventory. Venous blood samples were collected for serum metabolite measurements. Levels of kynurenic acid (KYNA), quinolinic acid (QUIN), tryptophan (TRP), 3-hydroxykynurenine (3-HK), kynurenine (KYN), and 3-hydroxyanthranilic acid (3-HAA) were measured using liquid chromatography-mass spectrometry (LC-MS).

Results: We found that GAD patients performed significantly worse in terms of the number of categories completed on the WCST ($p=0.014$), TMT-A ($p<0.001$), TMT-B ($p=0.015$) and Stroop Test sub-scores ($p<0.001$) compared to the healthy control group. GAD patients had significantly higher QUIN levels and a lower KYNA/QUIN ratio ($p<0.001$) than the healthy control group, while the control group had a higher 3-HK/KYN ratio ($p=0.008$). A negative correlation was found between DST scores and 3-HAA ($r = -0.311$, $p = 0.048$), as well as between the KYNA/KYN ratio and the stroop test subscore ($r = 0.368$, $p = 0.019$). In the GAD group, we found a positive correlation between kynurenine levels and state anxiety scores ($r=0.34$; $p=0.032$). In regression analysis, the KYNA/QUIN ratio significantly reduced GAD risk ($p=0.001$; OR: 0.531), independent of test performance.

Conclusions: Our study suggests that neurotoxic metabolites in the kynurenine-tryptophan metabolism may explain the executive function impairments observed in GAD. A key finding is that higher KYNA/QUIN ratios significantly reduce GAD risk, which

is etiologically important and provides valuable guidance for future research.

Effectiveness of Repeated Ketamine Infusions in Treatment Non-Responding Obsessive Compulsive Disorder: a Randomised Controlled Trial

L. Hauhnar[1]* and V. S. Mehta[2]

[1]Psychiatry, All India Institute of Medical Sciences (AIIMS), Gorakhpur and [2]Psychiatry, Central Institute of Psychiatry, Ranchi, India

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.273

Introduction: Though glutamate modulators have been increasingly used with some success in cases of OCD resistant to SRIs, there is limited data on the use of ketamine in OCD. There is one study on the use of multiple ketamine infusions in SRI-resistant OCD, but no studies have yet compared the effectiveness of multiple infusions of ketamine with multiple infusions of an active comparator agent. Benzodiazepines are commonly prescribed for OCD despite the lack of recommendations. The current study was a hospital-based prospective, single-blind, randomised controlled trial conducted over a period of one and a half years to compare the effectiveness of multiple infusions of ketamine with those of midazolam.

Objectives: To look into the immediate effects of ketamine infusion in terms of reduction in illness severity in OCD treatment non-responders in comparison to midazolam infusion.

To determine the time-point associated with the largest change in symptom severity in patients receiving repeated ketamine infusions in comparison to midazolam infusions.

To determine the overall proportion of response of OCD treatment non-responders to ketamine infusions in comparison to midazolam infusions.

Methods: In a hospital setting, we compared the effectiveness of 6 sessions of ketamine infusions (0.5 mg/kg body weight) with that of 6 sessions of midazolam infusions (0.045 mg/kg body weight), given on alternate days on a Monday-Wednesday-Friday schedule, in 30 patients with treatment non-responding OCD. Assessments were made using rating scales: DY-BOCS, MADRS, HAM-A, CADSS and SAFTEE.

Results: At 1 hour and 4 hours after the 1st ketamine infusion, 26% of patients achieved treatment response, while none in the midazolam group did so at these time points (Figures 1 and 2). Maximum symptom reduction occurred after the 1st infusion. By the 6th infusion, 40% of ketamine patients achieved treatment response, compared to 20% in the midazolam group. At 4 weeks after the last infusion, only 1 patient (6%) in the ketamine group maintained treatment response, with none in the midazolam group. Overall, the result indicates that the ketamine group showed significant improvement compared to the midazolam group (F=1.541, p=0.048) with a medium effect size (η2=0.056) (Fugure 3). There were no statistically significant differences between the two groups in terms of overall reductions in MADRS.

Image 1:

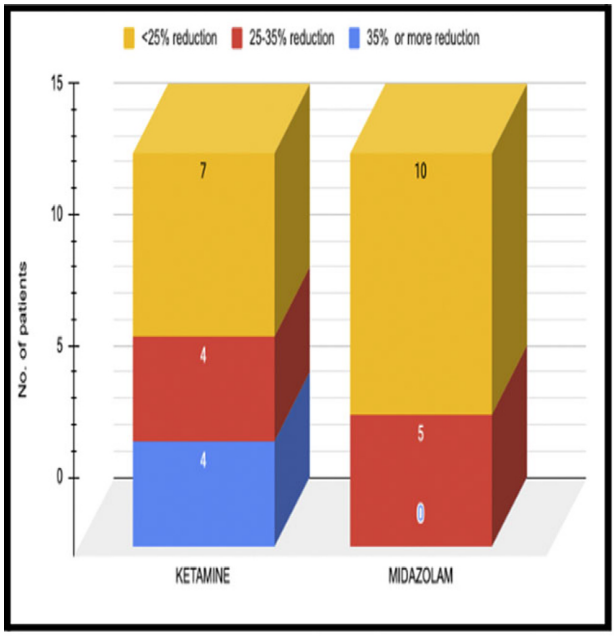

Figure 1: Stacked column chart showing the distribution of degrees of % reductions in DY-BOCS Global Score in ketamine and midazolam groups at 1 hour after 1st infusion.

Image 2:

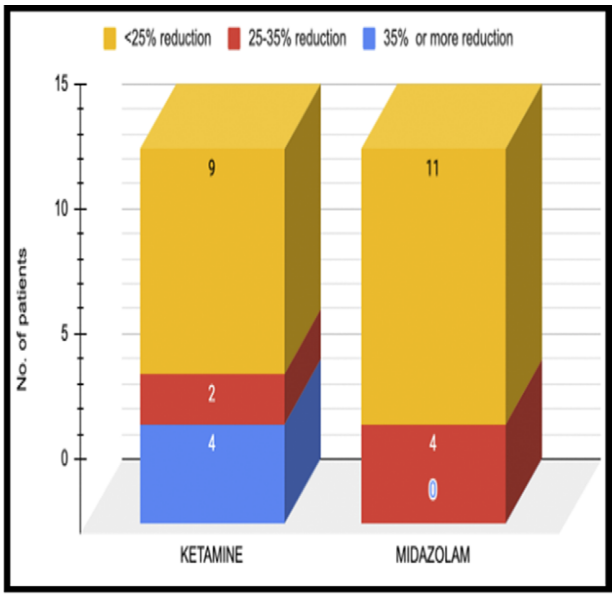

Figure 2: Stacked column chart showing the distribution of degrees of % reductions in DY-BOCS Global Score in ketamine and midazolam groups at 4 hours after 1st infusion.

Image 3:

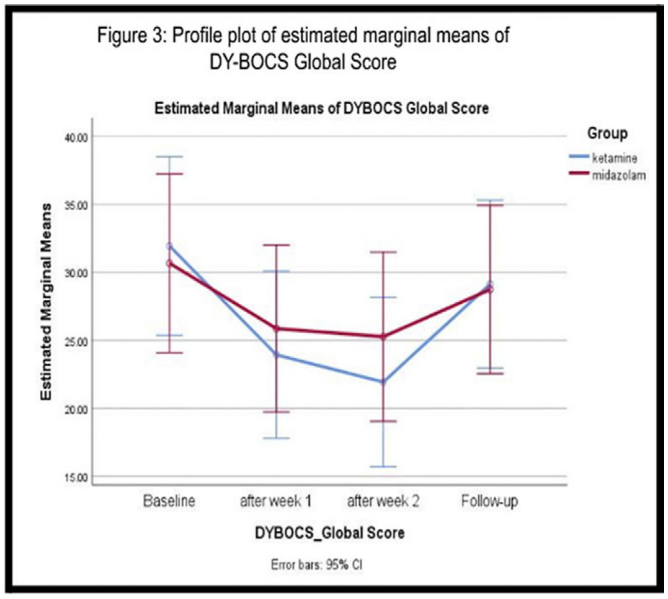

Figure 3: Profile plot of estimated marginal means of DY-BOCS Global Score

Conclusions: Ketamine, though modest in action, is superior to midazolam. Our findings lie between those of 2 prior studies—that by Bloch et al. (2012), who showed it to be largely ineffective, and that of Rodriguez et al. (2013), who found that half of their participants continued to show response even 1 week after the infusion. The differential overall improvement in DY-BOCS in the ketamine group over the midazolam group was independent of the reductions in depressive symptoms.

Deep brain stimulation (DBS) in patients with obsessive-compulsive disorder – a two-year follow-up on quality of life

V. Johansson[1,2*], P. Blomstedt[3] and M. Naesström[1]

[1]Department of Clinical Sciences, Psychiatry unit, Umeå University, Umeå; [2]Department of Medicine Solna, Centre for Pharmacoepidemiology, Karolinska Institutet, Stockholm and [3]Department of Clinical Sciences, Neuroscience unit, Umeå University, Umeå, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.274

Introduction: Deep brain stimulation (DBS) is a neurosurgical procedure in which thin electrodes connected to a neuro-pacemaker are implanted into deep brain structures to modulate pathological neuronal activity with electrical current. DBS is used for symptom relief in Parkinson´s disease (Groiss *et al.* TAN Disord 2009; 2 79–91) and is under investigation for several psychiatric conditions (Naesström *et al.* NJP 2016; 70 483–91). Severe and treatment-resistant obsessive-compulsive disorder (OCD) may be treated with DBS to achieve reduced OCD symptoms, ultimately aiming for an improved quality of life.
Objectives: Our objective is to present preliminary data on OCD patients' self-reported quality of life related to the development of OCD symptoms, before DBS surgery, and up to two years after surgery.
Methods: Patients with severe OCD (n=12) were enrolled in an open-label clinical trial on DBS delivered into the brain area of the bed nucleus of stria terminalis (BNST), as previously described (Naesström *et al.* W Neurosurg 2021; 149 e794-e802). The patients completed the EuroQOL five dimensions questionnaire (EQ-5D-3L) and were assessed with the Yale-Brown Obsessive Compulsive Scale (YBOCS) before DBS surgery and after six, 12, and 24 months. The paired *t-test* was used to analyze for group differences.
Results: The mean age at DBS surgery was 39.2 years (standard deviation [SD] 15.5) and the baseline YBOCS score corresponded to severe to extreme OCD (mean 33, SD 3.0). The mean EQ-5D index score was 0.62 (SD 0.11) at baseline and had improved to 0.74 (SD 0.13) at the two-year follow-up and the difference was statistically significant ($t = 2.8$, $df = 7$, $p\text{-}value = 0.025$). The EQ-5D VAS scores measured pre-surgery were low (mean 35.9, SD 22.2) and had increased two years post-surgery (mean 54.4, SD 21.0), but with no statistically significant difference ($t = 1.9$, $df = 8$, $p\text{-}value = 0.093$).
Conclusions: Quality of life in OCD patients two years after DBS surgery measured with the EQ-5D-3L showed an improvement two years following surgery for the EQ-5D index but not for the VAS scale. These preliminary data show that self-assessment with the EQ-5D-3L scale may be used to follow up on patients' quality of life after DBS and longer follow-up periods are warranted.

Effect of Nurse-Led Interventions in Reducing Post-Traumatic Stress Disorder Symptoms in Inpatients: A Systematic Review and Meta-Analysis

F. Oflaz[1] and N. D. Kılınç[2,3*]

[1]Koç University, School of Nursing; [2]Koç University, Institute of Health Sciences and [3]İstanbul Arel University, Faculty of Health Sciences, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.275

Introduction: Psychologically, traumatic incidents often involve physical injuries that threaten a person's survival and sense of security. After a sudden health problem or other kind issues, hospital admission can be an experience that negatively affects psychological health and recovery, often including symptoms of post-traumatic stress disorder, anxiety, and depression. Nurses who spend a longer

time with patients can determine the initial changes in individuals and play a crucial role in the decision-making process.
Objectives: This systematic review aimed to investigate the effect of nurse-led interventions in reducing post-traumatic stress disorder symptoms in inpatients.
Methods: In this review, we investigated studies from Pubmed, Cochrane Library, Medline (OVID), Scopus, Web of Science, CINAHL, Dergipark and TR Dizin (a directory) databases that met the inclusion criteria. The methodological quality of the studies was assessed using the Cochrane Risk of Bias 1 tool. This study was performed based on the Guidelines of Systematic Reporting of Examination presented in the PRISMA checklist. The search protocol has been registered at the PROSPERO International Prospective Register of Systematic Reviews.
Results: This systematic review included seven studies with a total sample size of 736 inpatients (intervention group: 350 participants; control group: 345 participants). The meta-analysis revealed that nurse-led interventions showed no statistically significant impact on post-traumatic stress disorder symptoms (SMD: -4,08, Z = .79, p = .43), anxiety (SMD: .28, Z = .18, p = .86) and depression (SMD: -.60, Z = .87, p = .38) in inpatients.
Conclusions: Out of seven studies, five of them indicated that these interventions were not effective in reducing PTSD symptoms while in two studies, the interventions were found to be effective in alleviating PTSD symptoms. To effectively reduce or prevent post-traumatic stress symptoms in inpatients, it is recommended to integrate a comprehensive range of therapeutic, evidence-based practices into clinical settings, facilitated by a multidisciplinary team approach within a educative and collaborative working environment.

Sleep debt in adolescence as a risk factor for depression in young adulthood

I. Morales-Muñoz[1]*, R. Amos[2], B. B. Durdurak[1], K. Gill[1] and S. Marwaha[1]

[1]Institute for Mental Health, School of Psychology, University of Birmingham and [2]Research and Development Department, Birmingham and Solihull Mental Health Foundation Trust, Birmingham, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.276

Introduction: Adolescence is a crucial stage, during which sleep undergoes significant maturation. Among the sleep changes that characterise adolescence, sleep debt is particularly relevant. Although existing evidence indicates that sleep debt is very prevalent in adolescents, little is known about its impact on adolescents' mental health.
Objectives: To explore the cross-sectional and longitudinal associations between sleep debt in adolescence and depression in adolescence and young adulthood.
Methods: This study is based on the Avon Longitudinal Study of Parents and Children. Here, we used data from 4,993 participants with information on sleep and depression at 15-16 years, and 3,962 on depression at 24 years. Self-reported information on amount of sleep hours per night during weekdays and weekends (i.e., actual sleep) and amount of sleep hours per night they felt they needed (i.e., sleep need) was collected at 15-16 years. Sleep debt at 15-16 years was calculated as the difference between sleep need minus actual sleep, with higher scores indicating higher sleep debt. Depression symptoms at 15-16 years were self-reported using the Short Mood and Feelings Questionnaires and the cut-off of total scores ≥ 8 was used as a criterion for depression. Moderate depressive disorder at 24 years old was measured using the self-administered computerised version of the Clinical Interview Schedule revised. To test the cross-sectional and longitudinal associations between exposures and outcomes, a series of logistic regression analyses (unadjusted and adjusted) were conducted.
Results: The results from the cross-sectional logistic regression analyses showed that the three measures of sleep debt (weekday, weekend and average) were significantly associated with the outcome, indicating that adolescents with higher sleep debt were at higher risk of concurrent depression at 15-16 years (weekday: OR=1.15, CI 95%=1.11-1.19, p<0.001; weekend: OR=1.04, CI 95%=1.01-1.07, p=0.010; average: OR=1.11, CI 95%=1.07-1.15, p<0.001). Regarding the longitudinal associations, only adolescents with higher sleep debt during weekdays were at higher risk of moderate depression at 24 years (OR=1.12, CI 95%=1.05-1.20, p<0.001), despite sleep debt on average being close to significant (OR=1.07, CI 95%=0.99-1.16, p=0.052).
Conclusions: Higher sleep debt is associated with higher risk of depression in adolescents and constitutes a risk factor for depression in young adulthood, particularly when the sleep debt occurs during weekdays. Our results contribute to the debate on early school times in adolescents and how these can impact their sleep patterns and consequently negatively affect their mental health. Further efforts to understand sleep debt in adolescence are needed, to prevent the development of future mental health problems.

The role of psychosocial stressors in PTSD development among medical staff in Ukraine

K. Golonka[1], S. Tukaiev[2]*, J. M. A. Ferreira[3], B. Palamar[4], K. Sitnik-Warchulska[1] and D. Fortuna[1]

[1]Institute of Applied Psychology, Jagiellonian University, Kraków, Poland; [2]Institute of High Technologies, Taras Shevchenko National University of Kyiv, Kyiv, Ukraine; [3]Faculdade de Medicina, Universidade de Coimbra, Coimbra, Portugal and [4]Department of Social Medicine and Public Health, Bogomolets National Medical University, Kyiv, Ukraine
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.277

Introduction: Prevalence of posttraumatic stress disorder (PTSD) has been documented in war-affected populations. A third of Ukrainians met diagnostic requirements for PTSD according to the UN, but the information on the mental health of medical staff is still insufficient. Well-known increased risk of mental disorder is

the result of traumatic experiences in healthcare workers as part of their professional duties.
Objectives: Based on this we aimed to analyze the potential sources of traumatic experience at work and the severity of PTSD and depression symptoms among medical staff in war condition.
Methods: The online and paper-pencil survey was conducted in November 2023 - January 2024. The study included a sample of 96 health care workers (doctors, nurses and paramedics). We used the structured interview on work characteristics of physical and psychosocial factors and standardized questionnaires on PTSD (Posttraumatic Stress Disorder Checklist; PCL-5) and depression (Patient Health Questionnaire; PHQ-9) symptoms. Additionally the needed source of support to cope with stress at work has been investigated.
Results: The correlation and regression analysis allowed revealing patterns between potential sources of traumatic experience at work and the severity of PTSD and depression symptoms among Ukrainian medical staff. The results of the correlation analysis of physical and psychosocial stressors, depression and PTSD symptoms indicated that psychosocial stressors define PTSD development. There were detected job-related specific psychosocial stressors among medical staff in Ukraine leaded to PTSD and depression development: "Conflict in organization/community", "Being threatened/abused", "Lack of appreciation by the organization/community in which you work".
Conclusions: The analysis identified the most important factors (psychosocial stressors) determining levels of PTSD in medical personnel at war. These data contribute to a significant debate on the negative role of job conditions at war for health care workers.

Open-label study: Exploring Culturally Adapted Psychosocial Programs for Haredi (Jewish Ultra-Orthodox) Parents of Children Exhibiting ADHD Symptoms

Y. Bloch[1]* and H. Dayan[2]

[1]Child and adolescent outpatient clinic & Research authority, Shalvata mental health Center, Hod Hashron and [2]Department of Community Mental Health, University of Haifa, Haifa, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.278

Introduction: Parent-focused interventions are an important part of the treatment plan for children with Attention-deficit/hyperactivity disorder (ADHD). Minority families tend to be less involved in psychosocial treatments and are more likely to discontinue the intervention. The Haredi community in Israel is a cultural-religious minority of 1.2 million people
Objectives: We aimed to assess the feasibility and potential efficacy of culturally adapted psychosocial programs for attention-deficit/hyperactivity disorder (ADHD) within the Haredi community in Israel.
Methods: This was an open-label non-randomized study conducted within the Haredi community in Israel between 2018 and 2021. The participants (N=265) were parents of children aged 8-12 years who had been diagnosed with ADHD or exhibited ADHD symptoms. Three culturally adapted programs were compared: 1. A program involving only the parents (N=46), 2. A program involving both children and parents (N=155) and 3. Only recorded video lectures with no interaction (N=38). Parents completed questionnaires to assess their self-efficacy using the Parenting Self-Efficacy tool (TOPSE) and their child's ADHD symptom severity, using the Vanderbilt ADHD Diagnostic Parent Rating Scale (VADPRS) both before and after the intervention.
Results: The programs demonstrated high feasibility. Of 335 referrals, 265 parents were recruited. Participation rates differed significantly between the video lectures program (60%) and the two interactive programs (80%, $p<0.001$). A significant interaction was found between time and program type for both parental efficacy ($F(2,213)=5.65$, $p=0.004$) and for ADHD symptomatology ($F(2, 213)=5.65$, $p=0.004$). Post hoc analysis revealed that the video lectures program showed no benefit, whereas both interactive programs (parents-only and parent-child) exhibited improvement in parental self-efficacy and reduction in reported ADHD symptom severity.
Conclusions: Despite certain limitations, this study suggests that culturally adapted psychosocial programs for ADHD in the Haredi community are feasible and that including an interactive component is crucial for effectiveness.

O011

Public Attitudes Towards Mental Health Stigma in Moldova: A Comparative Study

J. Chihai[1]* and V. Condrat[2]

[1]Mental health, medical psychology and psychotherapy, State Medical and Pharmaceutical University Nicolae Testemitanu and [2]IP Trimbos Institute Moldova, Chisinau, Moldova, Republic of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.279

Introduction: Mental health stigma remains a significant challenge in Moldova despite ongoing progress in mental health services. The negative perception and stereotypes about mental disorders have been socially ingrained, resulting in negative attitudes, fear, or even humor directed towards affected individuals. Addressing this stigma is essential to improve mental health outcomes and integrate services effectively.
Objectives: The study aimed to evaluate public perceptions and attitudes towards mental health stigma in Moldova, identify common stereotypes, and suggest actions to reduce stigma.
Methods: The research employed a comparative study design using a structured questionnaire across two different time points: 2018 and 2022. Data were collected through face-to-face interviews utilizing the Computer-Assisted Personal Interviewing (CAPI) method, ensuring data accuracy and consistency. The study covered eight districts, with a total sample of 2973 participants stratified by geographic region and demographic characteristics.
Results: The findings highlighted that the level of acceptance towards individuals with mental health issues was moderate, with participants showing more acceptance at a distance, indicating

persistent stigma. Notable differences between urban and rural areas were observed, with urban areas showing a higher level of openness. Furthermore, stigma was significantly influenced by the level of education and age of the respondents.
Conclusions: Mental health services are currently available across all districts of Moldova, but there remains a need for ongoing improvements to ensure equal access to high-quality care and to minimize both geographical and stigma-related barriers. Ongoing training programs for healthcare professionals are vital for effectively reducing stigma and improving the quality of care for those facing mental health challenges, with a specific focus on non-discriminatory practices and empathetic approaches. To achieve successful mental health care, a collaborative approach that involves healthcare professionals, policymakers, and community stakeholders is essential. This multidisciplinary coordination is key to establishing a supportive and comprehensive care environment. Additionally, public awareness campaigns and educational initiatives targeting both the general population and healthcare providers are critical in reducing stigma and changing attitudes towards mental health, thereby encouraging more people to seek care. Finally, integrating mental health services into primary healthcare should be prioritized to enhance accessibility and continuity of care. This integration will also facilitate early diagnosis and timely intervention, leading to improved outcomes for patients.

Suicide-related features in migrant people with a recent suicide attempt: Results from the SURVIVE Study

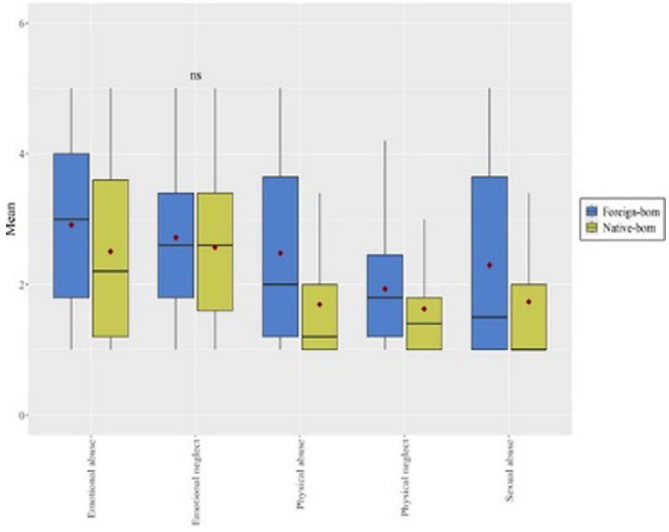
A. De La Torre-Luque[1,2*], M. Diaz-Marsa[1,2,3], Y. Sanchez-Carro[4], L. J. Gonzalez-Agudelo[1], M. Elices[5], M. Botí[6], A. Cebria[7], P. Saiz[8], M. Ruiz-Veguilla[9], P. Lopez-Peña[10], A. Gonzalez-Pinto[10], A. Palao[11] and V. Perez-Sola[5]

[1]Complutense University of Madrid; [2]CIBERSAM ISCIII; [3]Hospital Clinico San Carlos, Madrid, Spain; [4]La Concordia University, Montreal, Canada; [5]Parc Sanitari Hospital Mar; [6]Clinic Hospital, Barcelona; [7]Parc Tauli, Sabadell; [8]University of Oviedo, Oviedo; [9]Hospital Virgen del Rocio, Sevilla; [10]Hospital Araba Vitoria, Vitoria-Gasteiz and [11]La Paz University Hospital, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.280

Introduction: Migrant people may constitute a vulnerable population with an increased risk of suicide-related behaviour due to the accumulation of multiple risk factors, such as migration-related stress, the history of traumatic experiences and socioeconomic situation in the country of immigration.
Objectives: To study the prevalence of suicide attempts from migrant population in hospital emergency departments. Moreover, it aimed to study suicide-related outcomes, according to migration status.
Methods: Data from 754 patients (73.1% female; m= 40.23, sd= 15.72) with a recent suicide attempt from 10 Spanish hospitals were included. Assessment protocols were delivered within the 15 days after the index attempt. Suicide-related outcomes, clinical and sociodemographic factors were assessed by administering a wide range of clinical tools (C-SSRS, MINI, BIS-21, BSI, ACSS-FAD, CTQ).
Results: One in four patients was foreign-born, mostly being from Latin American countries (74% of foreign-born patients). Foreign-born patients were younger, higher psychopathology symptom severity, child trauma scores (Figure 1), than their counterparts ($p < .01$). Higher proportion of employed people and lower amount of people receiving pension benefits, were found in the foreign-born group. No between-group differences were observed regarding suicide-related outcomes. Finally index attempt in foreign-born group was featured by using more lethal methods ($p < .05$) (Figure 2).

Image 1:

Figure 1. Group differences in child trauma scales. Between-group differences were significant (p < .01), except for the Emotional neglect scale ('ns').



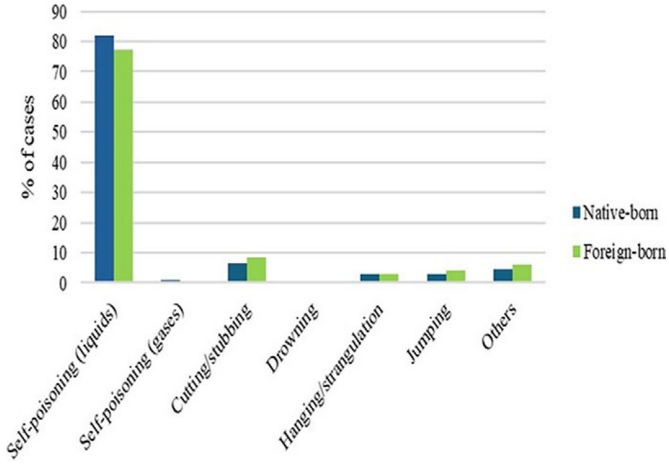


Image 2:

Figure 2. Method used for the index attempt, according to group.

Conclusions: Significant proportion of attempts attended in clinical settings may come from migrant people, mainly featured by child trauma history. Attempts from migrant populations may be featured by more lethal methods. Health care provision adjustment becomes mandatory to meet migrant people needs in current times.

The Role of Resilience on Correctional Worker Wellbeing: A Systematic Review

S. Lalji-Mawji[1,2*], P. Harris[1,2,3], W. M. Tomlin[4], M. O. Ahedor[4], B. Ostemeyer[4] and A. T. Olagunju[1,2,3,4,5]

[1]Michael G. DeGroote School of Medicine; [2]Psychiatry and Behavioural Neurosciences, McMaster University; [3]Forensic Psychiatry Program, St. Joseph's Healthcare Hamilton, Hamilton, Canada; [4]Psychiatry and Behavioural Neurosciences, University of Oklahoma, Oklahoma, United States and [5]Psychiatry, University of Adelaide, Adelaide, Australia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.281

Introduction: Correctional workers face uniquely stressful conditions that can impact their personal and professional wellbeing. Resilience, defined as the ability to adapt and thrive in adverse conditions, may be a key mitigator of occupational stress. Despite its potential benefits, few reviews examine the wellbeing of correctional workers (Miller, O., Bruenig, D., & Shakespeare-Finch, J. 2022; 49(11), 1559-1579) but have not comprehensively addressed resilience.
Objectives: 1. Describe resilience and summarize measures used to assess resilience in correctional settings. 2. Investigate the role of resilience on psychosocial wellbeing, burn-out, work performance, work leaves, attitudes, response to adverse incidents and turn-over among correctional workers. 3. Describe risk factors associated with resilience among correctional workers. 4. Describe study-defined strategies to build resiliency and relevant recommendations for future research and clinical practice.
Methods: The present review was conducted in accordance with Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guideline. Major databases (PubMed/MEDLINE, Embase, PsycINFO, Scopus, and CINAHL) were searched for eligible reports. At least two independent reviewers were responsible for screening and data collection. Conflicts were resolved via discussion, with input from senior authors when necessary. Quality appraisal was conducted for all included reports.
Results: As shown in Figure 1, a total of 679 articles were identified through major database searches. Title and abstract screening yielded 51 articles eligible for full-text review. The majority of articles were set in North American correctional facilities. Key factors for resilience included support systems, purpose, and optimism, while workplace adversity was a risk factor. Resilience was found to reduce symptoms of burnout and depression, and be crucial for managing psychosocial wellbeing. The presentation will discuss strategies to build resilience and highlight relevant recommendations.

Image 1:

Conclusions: Overall, resilience was found to play a mediating role in the wellbeing of correctional workers. Further studies involving a standardized measure of resilience and broader populations and correctional settings are required to improve the validity and generalizability of findings.

The European Violence in Psychiatry Research Group (EViPRG): what does it offer for a European psychiatrist?

T. Lantta[1,2,3*], S. Hirsch[4,5] and T. Hatling[6]

[1]Department of Nursing Science, University of Turku, Turku, Finland; [2]Centre for Forensic Behavioural Science, Swinburne University of Technology, Melbourne, Australia; [3]Department of Biomedical, Metabolic and Neuroscience, University of Modena and Reggio Emilia, Reggio Emilia, Italy; [4]ZfP Suedwuerttemberg, Ravensburg; [5]Ulm University, Ulm, Germany and [6]Norwegian resource center on community mental health, N/A, Norway
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.282

Introduction: The use of restrictive practices such as restraint, seclusion and long-term segregation on people with mental health problems remains common in European psychiatric care to

manage patients' violent and other challenging behaviour. These practices violate human rights and thus there is a growing international policy move to reduce or even ultimately stop using them. To achieve this, clinicians, researchers, teachers, trainers, policymakers and user representatives need to collaborate to transform psychiatric services towards non-coercive services. An international network provides one way towards this vision.
Objectives: Here we present an international network focusing on developing knowledge and practices aiming at reducing violence and coercion in mental health settings. We will illustrate how networking in an interdisciplinary group can be beneficial to both - European psychiatrists as well as other professionals in mental health services.
Methods: The EViPRG is a non-governmental research-focused network founded in 1997. Our vision is to work together to improve competency and quality of practice with the aim to reduce coercion and violence in mental health services, and address ongoing human rights issues. Clinicians in the psychiatric field as well as researchers can join the network through an electronic application (https://www.eviprg.eu/). Participation of early career researchers is encouraged.
Results: The EViPRG offers a unique network to connect with like-minded colleagues, collaborate on research projects, learn from various national initiatives to reduce coercion, exchange best practice models and take part in discussions via our various platforms. The network meets 3-4 times per year both in-person and online. Meetings provide an arena to present the latest research findings, generate new research projects and get feedback from colleagues. The EViPRG also organises the bi-annual "European Conference on Violence in Clinical Psychiatry" and members get a reduced fee to attend.
Conclusions: The network has more than 130 members in Europe and beyond. Numerous multi-country studies have been initiated through the network. As an example, in the years 2021-2024, a European Commission-funded project COST Action FOSTREN widened the network to new countries. As a result, we expect a rise in our membership, especially from Eastern Europe. If you want to find like-minded research partners and innovators, link in with a strong community aspiring to influence policy and practice in this area, progress your career and international profile, or just meet new colleagues, membership in the EViPRG can be your choice.

Climate Change

O015

From pre-existing vulnerabilities to daily stressors, what is the impact of climate change on mental health and gender inequity in Asia region?

V. Kaya[1], L. Clouin[1], T. Iglesias Zayas[1], K. Le Roch[2], R. Alessandri[1] and E. Dozio[3]*

[1]Operations; [2]Mental Health and Psychosocial Support and [3]Action contre la faim, Montreuil, France
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.283

Introduction: Background: While climate change affects millions of people in South and Southeast Asia, women and girls are disproportionately impacted, largely due to pre-existing vulnerabilities given their traditional gender roles and intensified adaptive capacity and sensitivity to climate change. They have often less representation and decision-making power in governance processes and structures involved in the development and implementation of climate change adaptation and mitigation policies. Moreover, they face mental health and psychosocial problems due to various climate-related stressors.
Objectives: The study aimed at exploring the perceptions of people living in contexts affected by climate change in order to better understand the impact on the psychosocial conditions of women and girls.
Methods: In 2023, online and in situ interviews were conducted with 30 individuals (15 women, 15 men) from the government, international and national organisations as well as academic and research institutions in Afghanistan, Bangladesh, Myanmar, Nepal, and Pakistan. Moreover, eight focus group discussions were conducted in Bangladesh (Kurigram and Sathkira districts) and Nepal (Rasuwa and Udayapur districts) with 71 community members, including 40 women and girls (aged 14 to 54 years old) and 31 men and boys (aged 15 to 70 years old).
Results: In Bangladesh, both districts face extreme weather like drought and floods, which leads to the migration of men. An increased involvement of women in farming, alongside their household responsibilities. This has transformed the family dynamic and women, as household head, have become the primary decision-makers. In Nepal, there has been a lack of awareness among women and men on the impact of climate change on their living conditions. The significant shift in the traditional gender divisions of labour has not brought an equitable transfer of assets and resources that could help women to cope after a climate-related event. Ultimately, women suffer from mental health issues.
Conclusions: This study shows some causal links between climate change and the psychosocial conditions of women and girls which confirm the necessity to develop gender-responsive climate change strategies, to improve access to mental health services and to prevent long-term changes within communities.

Mental Health, Loneliness and Urbanicity – A Cross-Sectional Network Analysis in a Nationally Representative Sample

D. Ochnik[1]*, M. Budziński[2], A. Szostak[2], Y. Vitkovskyi[2], M. Wierzbik-Strońska[1], E. Rojczyk[1] and P. Nagel[3]

[1]Medicine; [2]Social Sciences and Humanities and [3]Architecture, Civil Construction, and Applied Arts, Academy of Silesia, Katowice, Poland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.284

Introduction: With increasing urbanization, more people are exposed to mental health risk factors stemming from the urban, social or physical environment. However, research on the connection between urban living and mental health remains unclear.

Objectives: This study aims to explore environmental and social risk factors for mental health issues using network analysis.
Methods: The study was conducted among a nationally representative sample of 2,701 habitants of Poland (51% of women). The measurements used were PHQ-9, UCLA, Neighbourhood Cohesion (Neighbourhood Belonging and Social Cohesion), REAT 2.0 (Quality of architecture conditions in neighbourhood area), distance and frequency use of blue, green, and urban public areas, Self-Rated Health, Physical Activity, urbanicity, size of place of residence per person and sociodemographic survey (age, education, income). We used a sparse Gaussian graphical model (GGM) with a graphical lasso with an EBICglasso estimator.
Results: We showed that urbanicity and physical environment were linked to mental health issues via neighbourhood cohesion and loneliness in the estimated network. Depression and anxiety were the nodes with the highest centrality strength and expected influence. Blue and green areas usage also had high centrality strength. Urbanicity played an important role as a bridge between the network nodes and had a high strength score. Physical health with blue and green areas frequency use had the highest closeness centrality score.
Conclusions: We revealed the connections among mental health, loneliness, social cohesion, and various environmental factors, particularly urbaicity. This will enhance our understanding of mental health risks and protective factors.
This study is a part of the "Urbanization and Health"(NdS-II/SN/0391/2024/012) project financed by state budget funds granted by the Minister of Education and Science within the framework of the Science for Society II Program in Poland.

doi: 10.1192/j.eurpsy.2025.285

Introduction: Suicide remains a major cause of death in prison (Status report on prison health in the WHO European Region 2022). In comparison with adults from general population, incarcerated people are at increased risk of presenting suicide-related behaviours (Fazel S, *et al.* Lancet Psychiatry 2017; 4 946–52). Although certain studies have identified effective programs to reduce suicide in prison context (Carter A, *et al.* EClinicalMedicine 2022; 44 101-266), there is little evidence examining the relationship between moderators of effectiveness at individual and contextual levels.
Objectives: This study aims to review empirical research on moderators of effectiveness of interventions in prison to reduce suicide, summarizing effect sizes across studies.
Methods: For this systematic review and meta-analysis, we searched EBSCOhost, ScienceDirect, PubMed and ProQuest for articles published from 1990 to 2024. Elegible studies included those evaluating the effect of psychological interventions, delivered to adults during incarceration, on suicidal prevention. The impact of moderators covering bibliometric features (i.e. year of publication, country), methodological features of the study (i.e. sample size, mean age of participants, sex ratio, study design, assessment type and tools), suicide-related features (main outcome, previous suicide history), and other relevant variables (prison type and location, type and length of sentence) as well as psychological traits (alcohol or drugs misuse or other treatments) were also included. This review was conducted in accordance with PRISMA guidelines. Meta-analyses using random-effect models were used to pool effect sizes for moderators' outcomes. The protocol was pre-registered with PROSPERO, CRD42024538967.
Results: Of 7728 articles retrieved, 18 studies (1695 participants, 330 [19.5%] females, 756 males [44.6%], and 609 [35.9%] unknown) met the inclusion criteria. Mean ages were 32·0 years, and ethnicity data was not sufficiently reported to be aggregated. Type of prison was mostly public sector and located in rural areas. Studies were frequently conducted in UK (n=8; 44%) and used varying study designs; most frequently pre-post with no control group (n=9; 50%). On average, prevention programs in prison context were effective in decreasing suicide deaths, suicidal ideation and self-harm (n=14; 78%).
Conclusions: Findings suggest that explanations for efficiency of psychological interventions to prevent suicide behaviour and self-harm in prison context, are moderated by physical environment, individual and psychosocial factors. Future research identifying what factors moderate treatment outcomes in suicide and self-harm prevention within prison environments could help elucidate associated factors of efficiency, helping develop potential therapeutic actions.

Combining structural MRI with Polygenic Risk Scores to disentangle unipolar and bipolar depression: a multimodal machine learning study

T. Cazzella[1]*, F. Colombo[1,2], M. Acconcia[1], L. Fortaner-Uyà[1,2], F. Calesella[1], B. Bravi[1,2], I. Bollettini[1], C. Monopoli[1], S. Poletti[1,2], F. Benedetti[1,2] and B. Vai[1,2]

[1]Psychiatry and Clinical Psychobiology Unit - Division of Neuroscience, IRCCS San Raffaele Hospital and [2]Division of Neuroscience, University Vita-Salute San Raffaele, Milan, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.286

Introduction: The differential diagnosis between Major Depressive Disorder (MDD) and Bipolar Disorder (BD) heavily relies on clinical observation. However, the two disorders often show similar symptomatologic profiles, leading to high misdiagnosis rates. Reliable biomarkers are therefore crucial to accurately discriminate between MDD and BD and provide better treatments. In this

regard, Machine Learning (ML) could represent a turning point in the field precision psychiatry, given its capability of making single-subject level predictions.
Objectives: In the present work, we aimed at providing a biomarker-based differential diagnosis between MDD and BD. To that end, we implemented: *i)* a structural MRI-based ML model; ii) a combined ML model, trained on MRI data and Polygenic Risk Scores (PRS) for different psychiatric disorders.
Methods: 168 depressed patients (73 MDD, 95 BD) were recruited at the IRCCS San Raffaele Scientific Institute. All patients underwent T1-weighted and Diffusion Tensor Imaging scans. Voxel-Based Morphometry (VBM) measures were extracted with Computational Anatomy Toolbox 12 (CAT12). Fractional Anisotropy (FA), Axial Diffusivity (AD), Mean Diffusivity (MD), and Radial Diffusivity (RD) were extracted with Tract-Based Spatial Statistics (TBSS). PRS for MDD, BD, Schizophrenia, Attention Deficit/Hyperactivity Disorder, Anorexia Nervosa and Autism were computed for a subsample of 155 patients (67 MDD; 88 BD) through Infinium PsychArray 24 BeadChip. We trained a Multiple Kernel Learning (MKL) algorithm with voxel-wise VBM and DTI features, subsequently combining them with the extracted PRS.
Results: The neuroimaging model achieved a Balanced Accuracy (BA) of 71.65% and an Area Under the Curve (AUC) of 0.77 (85.44% sensitivity, 57.86% specificity). All the features contributed to the prediction, with AD (63%) and MD (26%) as the most predictive. Adding PRS to neuroimaging resulted in an improved performance, reaching 74.18% BA and 0.77 AUC (90.97% sensitivity, 57.38% specificity). The most predictive features of the neuroimaging-PRS model were MD (56%) and AD (27%).
Conclusions: Structural MRI discriminated between MDD and BD, and adding PRS to neuroimaging features improved the performance of the ML model. These results highlight the predictive power of structural neuroimaging for the differential diagnosis between MDD and BD, as well as prompting multimodal classifiers as a promising tool in the context of precision psychiatry.

Neural Associations of Preclinical Alzheimer's Disease in Individuals with Low Anxiety Scores

U. Cikrikcili[1]*, B. H. Schott[2,3], U. Ay[4], T. N. Jockschat[5] and E. Düzel[1,6]

[1]German Center for Neurodegenerative Diseases (DZNE), Magdeburg; [2]German Center for Neurodegenerative Diseases (DZNE); [3]Department of Psychiatry and Psychotherapy, University Medical Center Goettingen, Goettingen, Germany; [4]Hulusi Behçet Life Sciences Research Laboratory, Neuroimaging Unit, Istanbul University, Istanbul, Türkiye; [5]Department of Psychiatry and Psychotherapy and [6]Institute of Cognitive Neurology and Dementia Research, Otto-von-Guericke University, Magdeburg, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.287

Introduction: Preclinical Alzheimer's disease (AD) is characterized by subtle cognitive changes that precede the onset of clinical symptoms. Neuropsychiatric symptoms such as anxiety have been increasingly recognized for their potential role in accelerating disease progression. Although various theories have been proposed, anxiety may exacerbate cognitive decline through mechanisms involving stress-induced neurochemical dysregulation, affecting brain regions vulnerable to AD pathology.
Objectives: This study examines the neural correlates of preclinical AD in individuals with low anxiety scores, employing MRI to explore potential early biomarkers and elucidate the complex role of anxiety in the progression of AD.
Methods: A total of 172 participants from the German Center for Neurodegenerative Diseases Longitudinal Cognitive Impairment and Dementia Study (DELCODE) were categorized into three groups: Healthy Controls (HC, n=59), Subjective Cognitive Decline (SCD, n=77), and Mild Cognitive Impairment (MCI, n=36). Anxiety levels were assessed using the Geriatric Anxiety Inventory-Short Form (GAI-SF), and neural responses to novelty were examined using 3-Tesla MRI. Statistical models were adjusted for relevant covariates, including age, education and study site. The differences of the three groups were analysed by one-way ANOVA contrasts and post-hoc analyses were performed with two sample t-tests.
Results: Significant neural differences were observed across groups, particularly in the precuneus, right angular gyrus, and right cerebellum exterior ($p < 0.001$, $p = 0.001$, and $p = 0.002$ respectively). The SCD group demonstrated greater activation in the right angular gyrus compared to HC ($p = 0.008$), while the MCI group exhibited more pronounced differences L-R precuneus, right cerebellum exterior, right angular gyrus, and right middle frontal gyrus regions indicating further cognitive decline ($p< 0.001$, $p< 0.001$, $p= 0.001$, $p= 0.017$ respectively).
Conclusions: This study identifies critical brain regions, with a particular emphasis on the right angular gyrus, associated with the early stages of AD in individuals with low anxiety scores. The activation in these areas likely correlates with an early inhibition deficit at the systems level in individuals with preclinical memory impairment. However, the role of anxiety in preclinical AD is complex and variable among individuals. Anxiety may serve as an early response to subtle cognitive changes in some, while in others, it might emerge as a consequence of these changes. Moreover, the relationship between anxiety and neural alterations in AD could be bidirectional, where anxiety both influences and is influenced by the disease's progression. These findings highlight the importance of considering anxiety when identifying early biomarkers for AD and suggest that targeted interventions addressing anxiety may help slow cognitive decline.

doi: 10.1192/j.eurpsy.2025.288

Introduction: Electroencephalography (EEG) has been extensively studied for decades in psychiatric research. However, its integration into clinical practice as a diagnostic or prognostic tool remains unachieved. We hypothesize that a key reason for this is the underlying heterogeneity among patients, which is often overlooked in psychiatric EEG research that relies on a case-control approach.
Objectives: The main objective of this study is to quantify the electrophysiological heterogeneity of psychiatric disorders.
Methods: We combine HD-EEG with normative modeling to quantify this heterogeneity using two well-established and extensively investigated EEG characteristics—spectral power and functional connectivity—across a cohort of 1,674 patients with attention-deficit/hyperactivity disorder, autism spectrum disorder, learning disorder, or anxiety, and 560 matched controls, see figure 1.
Results: Normative models revealed that deviations from population norms among patients were highly heterogeneous and frequency-dependent. The spatial overlap of deviations among patients did not exceed 40% for spectral power and 24% for connectivity. Taking individual deviations into account significantly enhanced comparative analysis and the identification of patient-specific markers, which showed a correlation with clinical assessments.

Image 1:

Conclusions: Our study underscores the necessity of moving EEG research in psychiatry beyond the group-level approach to achieve precision psychiatry.

MM120 (lysergide) in a controlled clinical setting: treatment of generalized anxiety disorder without co-occurring psychotherapeutic intervention

S. M. Karas[1], R. Barrow[1], C. Conant[1], J. M. Freedman[1], P. L. Jacobsen[1], J. Jemison[1], D. R. Karlin[1,2]* and T. M. Solomon[1]
[1]Mind Medicine, Inc., New York and [2]Department of Psychiatry, Tufts University School of Medicine, Boston, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.289

Introduction: Generalized anxiety disorder (GAD) is among the most common psychiatric disorders and has significant impairment on patients' daily life. Effective and well-tolerated pharmacotherapies are needed. The FDA has noted that the inclusion of psychotherapy within trials complicates assessment of psychedelic drug efficacy, although to date many psychedelic trials have included co-occurring psychotherapy.[1] Co-occurring psychotherapy confounds the evaluation of efficacy and may complicate commercial labeling. A phase 2b study of the dose response to single treatment MM120 (lysergide D-tartrate) suggests a safe, rapid, and durable dose-dependent response in participants with moderate-to-severe GAD[2] and design elements are examined herein.
Objectives: To examine the methodological use of Dosing Session Monitors (DSM) within MM120 treatment without co-occurring of psychotherapy.
Methods: This phase 2b (NCT05407064) multicenter, randomized, double-blind, placebo-controlled study enrolled adults aged 18 to 74 years diagnosed with moderate to severe GAD.[2] Two DSMs, meeting FDA recommended qualifications,[1] were assigned to a participant throughout the study duration. Prior to dosing, participants engaged in baseline study education with their DSMs. During dosing, DSMs provided assistance and comfort as needed and monitored the participant for safety. Starting at 8 hours post-dose, a pre-specified checklist to end the session was administered, although all participants were required to stay onsite a minimum of 12 hours. The follow up period for the trial was 12 weeks, and DSMs only followed up with participants at Day 2, Week 1, and Week 2 post-dose. DSM follow up focused on participant safety and did not include focus on producing post-synaptic change.
Results: In total, 198 participants were enrolled in the study. The phase 2b study demonstrated a statistically significant safe, dose-response relationship at the week 4, 8, and 12 primary and secondary endpoints.[1] Utilizing the prespecified checklist, 45% of participants receiving MM120 100µg met criteria for end of session at 8 hours post dose, with 87.5% achieving criteria at 10 hours.
Conclusions: The results demonstrate that a single treatment with MM120 produces a safe and durable clinical response without co-occurring psychotherapy. These findings indicate that MM120 treatment sessions may be safely shortened from a minimum of 12 hours to 8 hours for some participants, and psychotherapy does not appear to be essential for its safety and efficacy.

Affective Go/NoGo fMRI study of adults living with ADHD reveals differential BOLD activation in ACC, insula, and secondary visual cortex

J. M. Réthelyi[1]*, M. Baradits[1], B. Kakuszi[1] and P. Czobor[1]

[1]Department of Psychiatry and Psychotherapy, Semmelweis University, Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.290

Introduction: Attention-Deficit/Hyperactivity Disorder (ADHD) is a neurodevelopmental disorder that begins in childhood and persists into adulthood in 35-50% of cases, resulting in a prevalence of 2-4% in the adult population. The core symptoms are inattention, hyperactivity, and impulsivity, while emotional dysregulation is considered an associated symptom. Several lines of evidence support structural and functional brain imaging alterations in ADHD. Decreased volume of the accumbens and amygdala persist from childhood into adulthood, and several resting-state and task-related functional alterations have also been reported.
Objectives: To investigate differential brain activation patterns in adults diagnosed with ADHD as compared to healthy controls (HC) during an affective Go/NoGo task, to understand the neural background of selective inhibition in emotionally demanding situations.
Methods: Data of 61 subjects were analyzed: 34 adult ADHD patients meeting DSM-IV diagnostic criteria (17 women, 17 men, mean age 37.3 years) and 19 HCs (10 women, 9 men, mean age 30.2 years). HCs were screened using the 90-item Symptom Checklist to exclude current psychiatric comorbidity. Symptom severity was assessed using the Conners' Adult ADHD Rating Scale (CAARS). During the MRI scan in a Philips Achieva 3.0T scanner, we used a block design delivering positive, negative and neutral stimuli from the IAPS System applying a Go/NoGo paradigm. The fMRI analysis focused on contrasts between task and rest, emotional and neutral, and Go and NoGo conditions (activation or deactivation). Contrast between activation and deactivation in the ADHD and HC groups were tested.
Results: Based on the pooled data from both groups, we found significant contrasts between the task and rest conditions, including an activation of primary and secondary visual cortex, frontal areas, corresponding to the Visual Network (VN), the Dorsal- and Ventral- Attention Networks (DAN, VAN), and the Central Executive Network; and a deactivation of the anterior cingulate, precuneus and parietal areas, corresponding to the Default Mode Network (DMN). During emotional vs neutral conditions, we detected activation of the secondary visual cortex, while contrasts between NoGo vs Go conditions manifested as activation of ACC and insular regions. ADHD subjects showed increased BOLD activation in the DAN and VAN areas. In all conditions, DMN areas showed higher deactivation in the ADHD group.
Conclusions: Here, we report differences in VN, DAN and VAN brain regions and the DMN in adult ADHD patients suggestive of distinctive pattern of activation and deactivation during an emotional Go/NoGo task. The results have clinical implications for understanding ADHD patients under in emotionally demanding situations.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.291

Introduction: The prevalence of depressive symptoms and cognitive decline increases with age. Understanding the temporal dynamics of these symptoms could provide valuable insights into the early stages of cognitive decline, allowing for more timely and effective treatment and management.
Objectives: Our objective was to explore how depressive symptoms, apathy, limitations in daily life activities, and cognitive impairment evolve and interact over time in older individuals. Specifically, we aimed to determine whether changes in these symptoms could help identify subsequent cognitive decline. We used Dynamic Time Warping analysis to model and characterize the progression of these symptoms, examining their relationships both at individual and group levels.
Methods: Participants from the Prevention of Dementia by Intensive Vascular Care (preDIVA) trial cohort with baseline and ≥3 follow-up measurements were included, with a median of 6.7 years of follow-up. Dynamic Time Warping analysis was used to model temporal dynamics of individual constituents of the Mini Mental State Exam (MMSE), activities of daily living (ADL) using the Amsterdam Linear Disability Scale (ALDS) and depressive symptoms using the 15-item Geriatric Depression Scale (GDS-15).
Results: The 1537 participants had an average age of 74 years at baseline, 56.5% were female, and 19.9% had finished a higher education. The directed analyses revealed a nuanced temporal pattern, wherein certain depressive symptoms preceded cognitive decline indicators, and vice versa. The GDS-15 symptoms with the

strongest outstrength, meaning changes in these symptoms preceded subsequent changes in other items, were the apathy symptoms 'dropped activities/interests', 'energetic' and 'not doing new things' (all p's<.001). The MMSE constituents with the strongest instrength, meaning changes in these symptoms were preceded by changes in other items, were 'immediate memory', 'verbal comprehension' and 'naming objects'. Decline in ADL function was a consistent predictor of worsening of depressive symptoms and cognitive decline (p<.001).

Image 1:

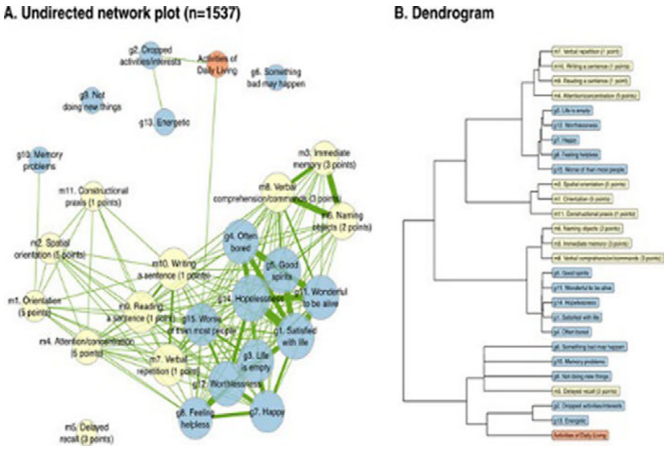

Image 2:

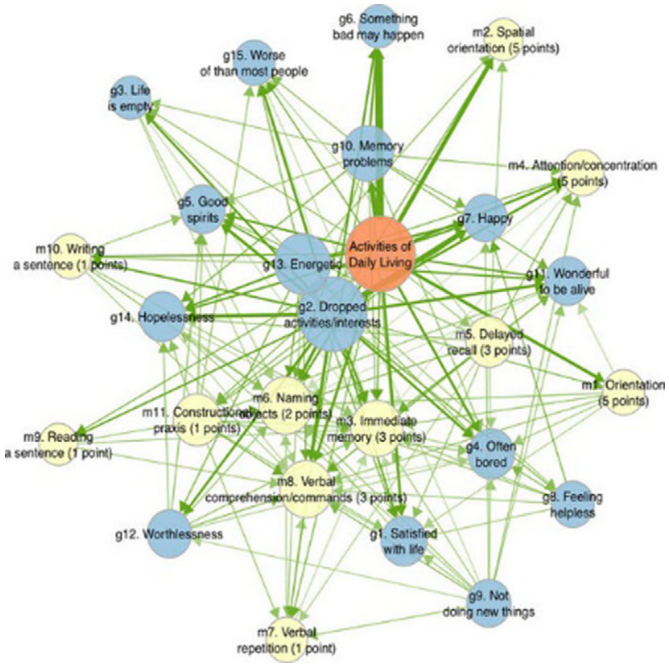

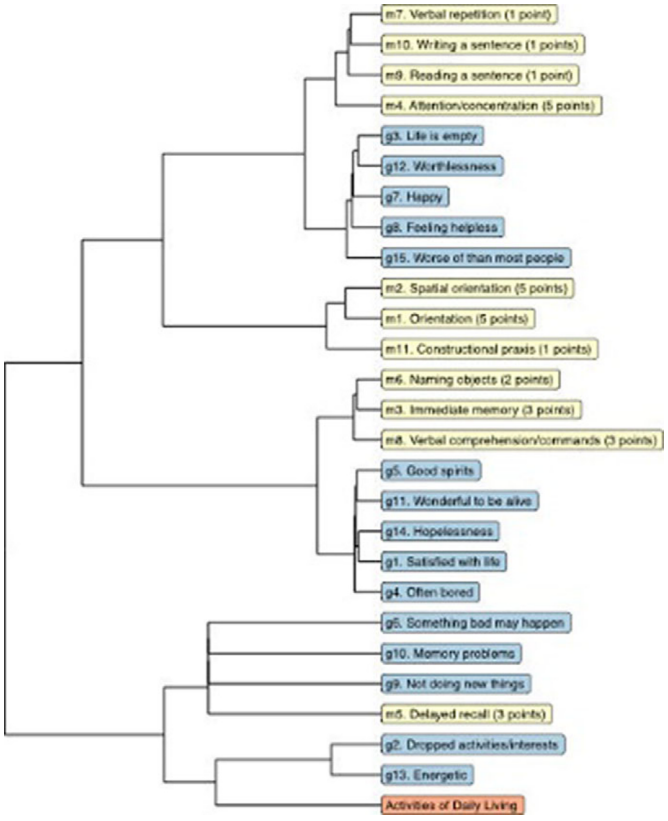

Image 3:

Conclusions: An increase in apathy and a decline in ADL preceded mood-related symptoms and cognitive impairment in older people aged 70-78 years.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.292

Introduction: Mental disorders, such as Bipolar Disorder (BD), Schizophrenia (SZ), and Schizoaffective Disorder (SA), are prevalent and often debilitating conditions that significantly impact

individuals' lives (Scangos et al. Nat Med 2023; 29(2): 317-33). Recent findings have identified blood RNA editing gene modifications that may aid in distinguishing between healthy controls, depressed patients, and those with BD and unipolar depression, improving diagnostic accuracy and treatment strategies (Salvetat et al. Transl Psychiatry 2022; 12(1):182).
Objectives: This study demonstrates that RNA editing biomarkers can accurately differentiate individuals with SZ, SA, BD, and healthy controls, highlighting the potential of artificial intelligence (AI)-based predictions for diagnosis.
Methods: A comparative analysis was performed with 85 healthy controls subjects, 39 BD, 31 SZ, and 14 SA patients. Patient samples were collected from two cohorts. Diagnostic assessments were conducted using SCID-1, HDRS, YMRS, and M.I.N.I., while healthy controls had no history of mental disorders or psychotropic medication use.
Results: Significant biomarkers were combined using a multiclass Random Forest algorithm. The algorithm was trained on 70% of the population. Then, the test was performed on the 30% of the population who never saw the algorithm. The analysis shows clear differentiation between the control group and individuals with BD, SZ, and SA with high sensitivities and specificities for ROC area under the curve (AUC).
Conclusions: This proof-of-concept analysis provides strong evidence for using RNA editing signature in diagnosis, and potentially in prognosis and treatment prediction. Further validation will be performed using a larger cohort.

Unraveling the Link Between Borderline Personality Disorder and Attention Deficit Hyperactivity Disorder

V. A. Barata[1]* and P. Gonçalves[1]

[1]Hospital Professor Doutor Fernando Fonseca, Amadora, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.293

Introduction: Attention Deficit Hyperactivity Disorder (ADHD) and Borderline Personality Disorder (BPD) are common psychiatric conditions, with comorbidity rates ranging from 18% to 34% in adults. Both disorders share symptoms such as impulsivity, emotional dysregulation, and interpersonal dysfunction, complicating differential diagnosis. Their frequent co-occurrence may suggest overlapping developmental and environmental risk factors as well as common underlying mechanisms. Particularly for BPD patients, recognizing the shared characteristics between ADHD and BPD may help reduce the stigma surrounding this disorder and eventually lead to a broader range of pharmacological treatment options.
Objectives: This review aims to explore the links between ADHD and BPD, focusing on their symptomatology overlap, comorbid presentation, shared risk factors and treatment insights in adults.
Methods: A narrative literature review was conducted using the keywords "ADHD", "borderline personality disorder", "comorbidity" and "adults" in PubMed and Google Scholar databases.
Results: Findings reveal that ADHD and BPD share several risk factors, including genetic predispositions and early-life adversities. Early-life adversity, particularly trauma, is a shared risk factor; however, the type and timing of adversity seem to play differential roles in developing ADHD and BPD symptoms. In terms of clinical presentation, ADHD is characterized by more severe impulsivity compared to non-comorbid BPD, whereas BPD features more severe difficulties in emotional regulation compared to non-comorbid ADHD. The comorbid ADHD +BPD presentation is marked by heightened severity in both impulsivity and emotional instability. The traditional view of ADHD as an early-onset disorder and BPD as a late-onset personality disorder is increasingly questioned, prompting calls for a dimensional diagnostic approach. Recent studies highlight the potential of ADHD medication, particularly stimulant compounds, in reducing suicidal behavior among BPD patients exhibiting ADHD symptoms. Such medications have been found to lower the risk of suicidal behavior in these patients, while other treatments (e.g., antidepressants, antipsychotics, mood stabilizers) did not show similar protective effects.
Conclusions: This review highlights the complex interplay between ADHD and BPD, emphasizing that both disorders should be considered within a dimensional framework rather than as separate categorical entities. Shared symptoms and risk factors underscore the need for integrated treatment approaches that address the combined symptomatology of ADHD and BPD. Future research should focus on understanding the developmental trajectories of these disorders, refining diagnostic criteria, and evaluating the effectiveness of combined treatment strategies.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.294

Introduction: Borderline Personality Disorder (BPD) remains a challenging and complex disorder but it can be successfully treated. In 2013, the first portuguese BPD specialized treatment programme was created in the Psychiatry Department at Local Health Unit of São João, becoming a very useful tool in the patients' management.
Objectives: We aim to study the influence of clinical characteristics on the duration of intervention and discharge from this BPD treatment programme.
Methods: Retrospective observational study of patients admitted to this programme until August 31st 2024. Descriptive analysis of the results was performed using the SPSS software, version 29.
Results: A total of 157 BPD patients were admitted to this programme, 154 (98%) of which are female. These patients had a mean age of 24,6 years old, when they engaged in the programme. During the follow-up 39% have abandoned the programme, and 27% have been discharged due psychotherapeutic stabilization.

We will also present results related to association between clinical factors (namely previous diagnoses and history of use of substances) and the duration of the intervention/discharge plan, in order to know if our results are consistente with the ones from another centers where comorbidity with eating disorders and cocaine use disorder were clinical variables predictors of shorter duration of the intervention.
Conclusions: Understanding the influence of clinical factors and their impact on intervention is essential to enhance this challenging programme to improve the treatment of BPD patients.

Religion: Coping Mechanism or Stressor? A Study of American Male-Factor Infertility Patients

A. Garcia Keeme-Sayre[1]*, J. Kassab[2], A. Oppenheimer[1], M. Duan[1], J. Huang[3], B. Stocks[3] and L. Lipshultz[3]

[1]Baylor College of Medicine, Houston; [2]Texas Tech University Health Sciences, Lubbock and [3]Urology, Baylor College of Medicine, Houston, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.295

Introduction: Seeking treatment for infertility is an emotional process, often provoking symptoms of anxiety and depression in both men and women, especially when treatment fails (Milazzo et al, Plos One; 11). While religion may provide hope and comfort to men with infertility, it may also provoke anguish in those whose religious doctrines restrict certain treatments.
Objectives: The goal of this study is to assess the role of religion in male patients' ability to cope with their infertility.
Methods: An electronic survey was sent to male patients who presented for an infertility visit at an American urology clinic. Using a 4-point Likert Scale, participants reflected on their religion's role in seeking treatment for infertility, their selection of treatment, and their ability to cope with their diagnosis. The Likert Scale results were analyzed utilizing T-tests via SPSS Software to assess answer variations across religions. Written responses were analyzed for common themes.
Results: 73% of respondents (n=288/395) identified with a religion (58.6% Christian, 29.5% Catholic, 11.8% Other Religion). Across all religions, participants reported that religion served as a significantly greater source of coping than of anxiety in their infertility treatment (2.56 vs. 2.03, t-value = 5.64, p-value = <.00001). In comparison with most other religions, Jewish participants (all non-orthodox) were significantly less likely to report their religion having any effect on their coping at all. Among those written responses that attributed their religion with their ability to cope, the most common key words were "prayer," "comfort," and words referring to religious community such as "pastor" (Table 1). Most written responses that indicated their religion had a negative emotional impact stated discomfort with a specific treatment or aspect of the treatment process. Of patients who discussed having disagreed with or gone against their religion's views (7.9%), the majority were Catholic (n=13/17 (76.5%)).

Image 1:

Table 1. Example written responses that attribute religion to coping with male-factor infertility

Key Word	Example Written Response	Religion
Prayer	"Religion . . . has helped with [my] coping ability. Daily prayer includes asking for successful fertility treatment, asking for a healthy baby, and asking for support of my wife during the difficult journey."	Catholic
Comfort	"My religion . . . was more a comforting influence for me and my spouse on the trauma of not easily producing a child."	Protestant Christian
Religious Community	"I believe that God put scientists and pastors here to help us deal with the world situation. Science to open new paths for healing and pastors to help with the emotional upheaval of everyday life."	Nondenominational Christian

Conclusions: Religion appears to be a source of coping more than anxiety for males with infertility. This is perhaps less applicable to non-orthodox Jewish patients. Providers of male-factor infertility treatment should practice sensitivity when presenting infertility treatment options as a minority of patients may experience cognitive dissonance when considering treatment at odds with their religious identity. However, in religious patients struggling with mental health due to their infertility, physicians can encourage spiritual health and connection with religious community.

High-Definition Transcranial Direct Current Stimulation-Primed Intermittent Theta Burst Stimulation in Treatment of Negative Symptoms of Schizophrenia - A Randomised Sham Controlled Study

R. Gupta[1]* and A. Sharma[1]

[1]Psychiatry, Central Institute of Psychiatry, Ranchi, Ranchi, India
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.296

Introduction: Negative symptoms of Schizophrenia (NSS) consists of apathy, avolition, anhedonia, social withdrawal, reduced expression (blunted affect and alogia) and impairments in attention, working memory, or executive function. Unfortunately, treatment effects of conventional approaches with antipsychotics, other

pharmacological agents or psychosocial interventions are limited and have not shown much improvement in reducing negative symptoms. Non-Invasive brain stimulation such as repetitive transcranial magnetic stimulation (rTMS) & high-definition transcranial direct current stimulation (HD-tDCS) offers a novel approach in the treatment of negative symptoms but with no agreed upon treatment protocol. Priming is a technique that can enhance the sensitivity of the brain to therapy using techniques that increase or decrease the excitability of the cortex. Preconditioning TDCS have shown profound impact on the conditioning effects induced by subsequent administration of rTMS in a few studies done in patients with depression. There has been no study assessing the effects of HD-tDCS primed iTBS in Negative Symptoms of Schizophrenia.
Objectives: The aim of this study was to evaluate whether HD-tDCS priming improves the efficacy of intermittent theta burst stimulation (iTBS) in improving the NSS.
Methods: A prospective hospital based randomized controlled study with a sample size of 40, where the participants were divided into Active or Sham HD-tDCS primed iTBS stimulation groups for a total of 20 sessions over two weeks. Assessments on clinical parameters at baseline, end of 2 weeks, and end of 4 weeks were done.
Primary outcome of the study was the differences in Positive and Negative Syndrome Scale for Schizophrenia (PANSS) & Scale for Assessment of Negative Symptoms (SANS) scores over 4 weeks of HD-tDCS primed iTBS between the two groups.
Results: There was a statistically significant reduction noted in the mean PANSS & SANS scores across all domains over time up to 4 weeks in both the active and sham groups.
Though there was more reduction in mean scores in total PANSS score as well as across domains, the difference between the two groups was not found to be statistically significant in any of the PANSS score. However, the difference was found to be significant for SANS total score and SANS attention score with score showing more reduction in the active group in comparison to the sham group.
Conclusions: These results suggest that the HD-tDCS primed iTBS had a superior effect specifically on negative symptoms, as reflected in the SANS scores, but not on the broader spectrum of symptoms measured by PANSS, which suggests that priming iTBS with HD-tDCS may prove to be beneficial in reducing the Negative Symptoms of Schizophrenia more effectively than iTBS alone.

Association between genetic proxies for neuroticism and labour market outcomes

A. Hazak[1,2,3,4]*, J. Liuhanen[1,5,6], K. Kantojärvi[1,5,6], S. Sulkava[1,5,7], T. Jääskeläinen[1], V. Salomaa[1], S. Koskinen[1], M. Perola[1,8] and T. Paunio[1,5,6]

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.297

Introduction: Neuroticism, defined by a tendency to experience negative emotions such as anxiety and irritability, has significant public health implications, affecting both mental and physical health. It is also associated with poor career outcomes, including lower job satisfaction and higher rates of occupational failure, highlighting its importance in understanding labour market disparities. Despite advances in genetics, including insights into genetic background for neuroticism through large genome-wide association studies, the relationship between genetic predisposition to neuroticism and labour market performance remains underexplored.
Objectives: This study examines the association between polygenic score for neuroticism (Nagel et al. *Nat Genet* 2018; 50 920-927) and individual labour market performance over 25 years in Finland. We aim to uncover how genetic predisposition to neuroticism relates to socio-economic outcomes, contributing to a broader understanding of its public health and economic implications.
Methods: Our analysis draws on pooled data from the Finnish Finrisk (1992-2012) and FinHealth (2017) studies, comprising a representative sample of adults aged 25-64 (N=20,121). We integrated genetic, survey and socio-economic registry data. Using probit and semi-structural regression models, we assessed labour market outcomes, with neuroticism polygenic scores as the primary explanatory variable. Controls for socio-demographic factors and genetic principal components were included.
Results: Individuals with higher polygenic scores for neuroticism were found to have lower income, partly through a direct and partly through a mediated association. Higher polygenic risk for neuroticism was linked to a decreased likelihood of completing higher education. Additionally, our study provides novel insights into how elevated polygenic risk for neuroticism was linked to labour market status.
Conclusions: Our findings demonstrate that genetic predisposition for neuroticism is not only associated with educational setbacks but also translates into labour market disadvantages. While the effect sizes are modest, our results suggest that compensatory measures and support may help mitigate the career disadvantages faced by individuals with a higher genetic risk for neuroticism.

Transcranial magnetic stimulation in obsessive-compulsive disorder – a prospective observational study

I. Palma[1]*, J. Borges[1], A. L. Ramos[1], E. Palha[1], H. Salgado[1], P. Alves[1], P. Sousa Martins[1] and R. Moreira[1]

[1]Psiquiatria, Unidade Local de Saúde de São João, Porto, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.298

Introduction: Obsessive-compulsive disorder (OCD) has an estimated prevalence of 1-2% and causes a significative reduction in functionality and quality of life with a high socioeconomic impact. First and second line treatment includes serotonin reuptake inhibitors, clomipramine, antipsychotics augmentation strategy and cognitive behavioural therapy. It is ineffective in 20-60% of patients whose approach may include transcranial magnetic stimulation (TMS).
Objectives: The aim of this study is to assess the effect of treatment with TMS on obsessive-compulsive, anxious, and depressive symptoms in patients with OCD.
Methods: A prospective observational study was conducted including all patients diagnosed with OCD who underwent TMS in our department since March 2023.
Our protocol targets the dorsolateral prefrontal cortex and includes a total of 25 sessions using the Food and Drug Administration approved parameters (20 Hz, 100% of the leg resting motor threshold, 50 trains of 2s duration, inter-train interval 20s, 2000 pulses per session). Before each session, symptom provocation is performed. TMS was performed using the Cool D-B80 coil and a MagPro stimulator.
Symptoms before and after treatment were assessed using the Yale Brown Obsessive-Compulsive Scale (Y-BOCS), the Hamilton Anxiety Rating Scale (HAM-A) and the Hamilton Depression Rating Scale (HAM-D).
Results: As of 01/09/2024, 21 individuals with OCD completed TMS treatment, 57% male, with a median age of 37 years (interquartile range (IQR) 17). The median duration of illness was 25 years (IQR 15), with 24% of patients having very severe OCD, 52% severe, and 19% moderate—all refractory to psychotherapeutic and pharmacological treatment.
There was a statistically significant reduction in Y-BOCS scores (pre-TMS median score 29 (IQR 6), post-TMS 21 (IQR 13), p=0.003), with 32% of patients achieving a complete response (Y-BOCS reduction ≥35%) and 5% a partial response (Y-BOCS reduction ≥25%). No correlation was found between the change in Y-BOCS scores and other variables such as age, duration of illness, and pre-TMS scores on Y-BOCS, HAM-A, and HAM-D.
Additionally, a statistically significant reduction was observed in HAM-A scores (pre-TMS median 20 (IQR 18), post-TMS 16 (IQR 11), p=0.026) and HAM-D scores (pre-TMS median 19 (IQR 17), post-TMS 15 (IQR 14), p=0.029).
No severe adverse effects were reported.
Conclusions: This study shows significant reductions in Y-BOCS, HAM-A, and HAM-D scores after TMS treatment, with many patients achieving complete or partial response. These findings align with previous research, suggesting TMS is an effective option for treatment-refractory OCD. The absence of severe adverse effects supports its safety.
In conclusion, this study adds to real-world evidence by demonstrating the efficacy and safety of TMS in a clinical setting. Continued data collection is crucial to identify predictors of response.

Scars of War: Unveiling the Psychiatric Consequences of Conflict and Trauma

A. Sousa[1]*, J. L. Guimarães[2] and M. F. Fernandes[2]

[1]Serviço de Psiquiatria e Saúde Mental, ULS Castelo Branco, Castelo Branco and [2]C.R.I. de Saúde Mental, Unidade Local de Saúde de Castelo Branco, Branco, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.299

Introduction: War and conflict have significant long-term effects on mental health, affecting both civilians and military personnel. Exposure to armed conflict greatly increases the risk of psychiatric disorders such as PTSD, depression, and anxiety. These effects are not limited to the immediate aftermath but can persist for years, even across generations. Vulnerable populations, including children, women, and refugees, are particularly at risk, facing compounded mental health challenges due to prolonged exposure to trauma and limited access to support.
Objectives: This poster aims to:

1. Explore the psychiatric consequences of war and conflict.
2. Investigate the development of PTSD, depression, and anxiety in conflict-affected populations.
3. Assess the role of transgenerational trauma transmission and its epigenetic effects.
4. Highlight the role of resilience and psychosocial support in mitigating these effects.

Methods: Data were drawn from various studies examining populations affected by conflict across different regions. Key metrics included the prevalence of PTSD, depression, and anxiety, and the impact of traumatic experiences. The role of social support and resilience factors in mitigating psychiatric outcomes was also analyzed.
Results: The findings consistently demonstrate high rates of PTSD and other psychiatric disorders in individuals exposed to conflict. Mental health impacts are often prolonged, with many individuals showing persistent symptoms years after the initial trauma. Additionally, research on epigenetic changes suggests that trauma can be passed down to future generations, potentially affecting their mental health. However, protective factors such as strong social support and community resilience were found to buffer the negative effects of trauma in some cases.
Conclusions: War and conflict have profound and lasting psychiatric consequences. The prevalence of mental health disorders is

significant among affected populations, and these effects can be transmitted across generations. Interventions should focus on providing timely mental health care, building resilience, and addressing the broader societal impacts of trauma. Early identification and support are critical to reducing the long-term mental health burden in conflict-affected areas.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.300

Introduction: Neuromodulation technologies became the safe and effective alternative to treat psychiatric and neurological disorders. The current evidence from the up-to-date state in vagus nerve stimulation application in studies of emotional state modulation demonstrates a strong impact of vagus stimulation on the state of patients with a range of disorders. The normalizing effect of vagus nerve stimulation on abnormal sympathetic nerve activity may explain the beneficial effect on burnout, which is thought to be a manifestation of decreased vagus-mediated heart rate variability (HRV) under everyday stress.
Objectives: Considering all of the above, we aimed to explore the influence of a novel VNS stimulation protocol on emotional state, as well as highlighting specific features of the activation-related neurodynamics and the effects on HRV time, frequency and non-linear metrics.
Methods: 11 right-handed male volunteers aged 18-22 years participated in the 1st (EEG) study (6 persons-taVNS group and 5-SHAM) and 62 healthy volunteers 18-49 years old were recruited for 2nd (HRV) study (26-VNS group and 22–Sham). We used the combination of pleasant meditative classical music and a slow bi-polar wave of electrical non-invasive transcutaneous stimulation of auricular area (BrainPatch platform for non-invasive stimulation). Vagus nerve stimulation was arranged as a 4-day course. Psychological testing (State Anxiety, STAI; psychological stress level, PSM-25; severity of emotional burnout, MBI; depression, IDS) was carried out.
Results: Non-invasive stimulation was rated by the participants as a positive experience. We detected beneficial changes in the psychoemotional state of the respondents (improvement of mood, reduction of job related stress – emotional burnout). The increase of vagally mediated parameter RMSSD and decrease of LF/HF ratio has reflected the activation of parasympathetic nervous system (PNS) during stimulation. HRV effects of VNS turned out to be short-term, which was manifested in a drop in the value immediately after the stimulation. EEG analysis indicated a long-term effect of VNS. Increased alpha and beta rhythms (generalized growth in the frontal and posterior cortex) and gamma activity (frontal region) after a series of 4 VNS sessions may indicate the improvement of mental processes and creative thinking (attention, information processing and memory storage). Enhanced activation level was mirrored in an increased beta/alpha ratio.
Conclusions: Our data suggests that VNS has a normalizing effect on the psychoemotional state shifting "sympatho-vagal balance" to the functional optimum. EEG data showed the prolonged stimulating effect on the brain processes related to the cognitive functioning while attenuating the stress impacts at the same time.

Using Instagram to Promote Youth Mental Health: Feasibility and Acceptability of a Brief Social Contact-Based Video Intervention to Reduce Depression Stigma

D. Amsalem[1]* and S. Haim-Nachum[1,2]

[1]Department of Psychiatry, Columbia University, New York, United States and [2]School of Social Work, Tel Aviv University, Tel Aviv, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.301

Introduction: Depression is a leading cause of disability among youth, with stigma significantly hindering mental health service utilization. Untreated depression is associated with greater severity, poorer outcome, and cognitive impairment. In addition to structural barriers to service use, stigma towards mental health is a profound obstacle that impedes individuals from seeking needed services. Reducing stigma toward depression can improve perceptions of treatment and engage young individuals with depressive symptoms in behavioral services.
Objectives: This study evaluates the feasibility and acceptability of delivering brief video interventions, proven to reduce depression stigma, via Instagram to promote help-seeking among youth. We hypothesized that the intervention would be both feasible and acceptable, generating higher link clicks and lower cost-per-click (CPC) compared to control videos.
Methods: A two-week Instagram campaign in February 2024 targeted U.S. adolescents aged 14-22. The campaign featured a 60-second human-narrated personal story video, previously shown to reduce depression-related stigma. The video showcased a young individual sharing their experience with depression, misconceptions about treatment, and the support they received. Engagement metrics assessed included impressions (video displays), reach (distinct viewers), link clicks (engagement with mental health resources), and CPC (cost-effectiveness). These were compared to four control videos: AI-narrated personal story ("Control 1"), human-narrated educational text ("Control 2"), AI-narrated educational text ("Control 3"), and an un-narrated educational text with background music ("Control 4").

Results: All five videos successfully reached a broad audience, with a combined total of 808,000 impressions, 287,000 viewers, and 4,148 link clicks. The Human-Narrated Personal Story (Intervention) video was highly effective, achieving 874 link clicks and a competitive CPC of $0.92, outperforming three of the four control videos. The AI-Narrated Educational Text (Control 3) had the highest number of link clicks (985) and lowest CPC ($0.82), while the AI-Narrated Personal Story (Control 1) had the fewest link clicks (680) and highest CPC ($1.18).
Conclusions: The intervention video successfully engaged the target audience, supporting its feasibility and acceptability for broader dissemination. Instagram proves to be a viable platform for disseminating evidence-based mental health interventions aimed at reducing depression stigma among youth. The study supports the potential for using social media in public mental health strategies, though further research is needed to evaluate its impact on help-seeking behaviors and across diverse demographic groups.

Multi-Scale Functional Network Connectivity Mediates The Association Between Bullying Exposure and Distressing Psychotic-Like Experiences in Healthy Adolescents

P. Andrés Camazón[1]*, R. Ballem[2], J. Chen[2], V. Calhoun[2], J. Galvañ[1], L. Lopez[3], J. C. Pedrosa[3], B. Sáez[3], M. Alonso[3], J. Suárez[3], N. Cruz[3], M. Gonzalo[3], M. R. Lopez[3], B. Arribas[3], A. Iraji[2] and C. M Díaz-Caneja[1]

[1]Institute of Psychiatry and Mental Health, Hospital General Universitario Gregorio Marañón, IiSGM, CIBERSAM, ISCIII, School of Medicine, Universidad Complutense, Madrid, Spain, Madrid, Spain; [2]Translational Research in Neuroimaging and Data Science (Georgia State University, Georgia Institute of Technology, Emory University), Atlanta, Georgia, United States., Atlanta, United States and [3]Institute of Psychiatry and Mental Health, Hospital General Universitario Gregorio Marañón, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.302

Introduction: Bullying, deliberate aggression by a peer or group of peers in a power imbalance that favors the aggressor, is a frequent and preventable traumatic event during adolescence (Abregú-Crespo R et al. The Lancet Child & Adolescent Health 2024; 8:122–134). Mitigating its impact could be a viable strategy for psychosis prevention (Fraguas, D. et al. JAMA Pediatrics 2021; 175, 44–55). A better understanding of its influence on brain development during adolescence could be crucial for implementing effective interventions.
Objectives: To study the relationship between bullying exposure (BE), distressing psychotic-like experiences (DPLEs), and multi-scale functional network connectivity (msFNC) in the developing brains of 12-year-old adolescents.
Methods: We used cross-sectional data from 12-year-old adolescents from the Adolescent Brain Cognitive Development Study, which recruited a representative sample of healthy adolescents from across the United States. We fitted a linear mixed model to predict DPLEs (Prodromal Questionnaire-Brief Child Version) with BE (Peer Experience Questionnaire) as a predictor (n=10,388). We analyzed functional magnetic resonance imaging data with reference-informed independent component analysis and a canonical and replicable multi-scale intrinsic connectivity network template to extract whole-brain 5460 msFNC features (Iraji, A. et al. Hum Brain Mapp 2023 44, 5729–5748). We fitted 5460 linear mixed models to predict DPLEs with BE as a predictor and analyzed the mediation effect of each of the 5460 FNC features (n=5,409). All models were fitted with family and site as random effects, adjusted for covariates (age, sex, race, ethnicity, pubertal development, and family income), and corrected for multiple comparisons.
Results: BE was significantly associated with DPLEs (β=0.39, CI [0.37, 0.41], t(10362) = 41.00, p<.001, R^2=0.36, p<.000) (**Fig.1**). DPLEs were associated with msFNC predominantly between cerebellar, paralimbic, somatomotor, insulotemporal, frontal, temporoparietal, and central executive networks (**Fig.2**). The association between DPLEs and BE was primarily mediated by msFNC between the paralimbic, somatomotor, insulotemporal, frontal, and temporoparietal networks (**Fig.3**).

Image 1:

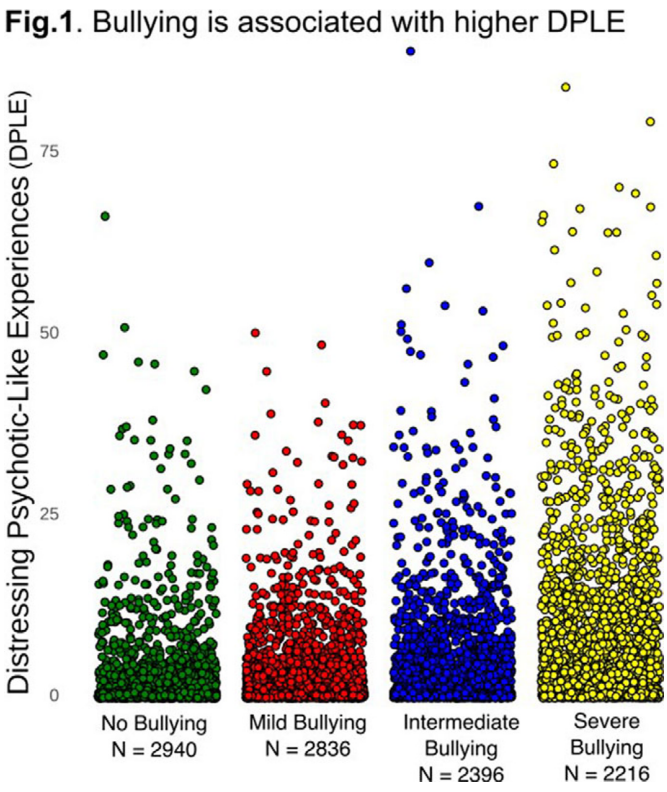

Image 2:

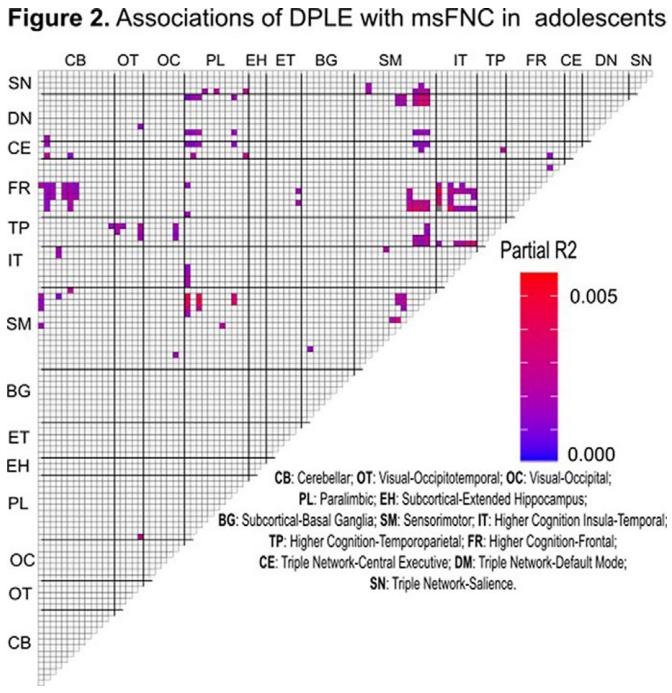

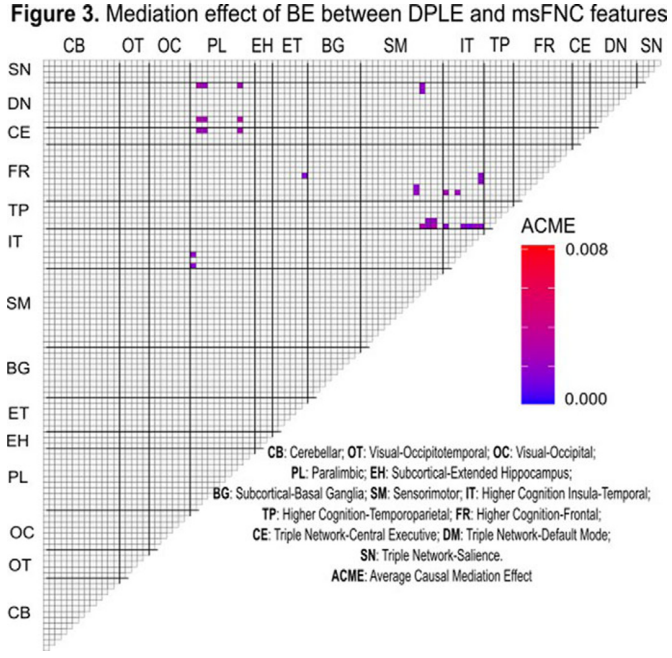

Image 3:

Conclusions: Bullying exposure may represent a modifiable risk factor for the development of DPLEs during adolescence. It may influence DPLEs through its effects on relevant functional brain networks. The implementation of targeted interventions to prevent BE during adolescence could serve as a viable strategy to mitigate potential functional brain alterations and reduce the risk of psychosis.

Landscapes of Recovery from Psychosis: Co-Creating Real-World Solutions in Urban Settings

L. A. A. Empson[1,2*], O. Söderström[3], M. Winz[3], J. Favrod[4], P. Golay[5], A. Ruggeri[3] and P. Conus[1]

[1]Service of General Psychiatry, Department of Psychiatry, CHUV, Treatment and early Intervention in Psychosis Program (TIPP); [2]Faculty of Biology and Medicine, University of Lausanne, Lausanne; [3]Geography Institute, Neuchâtel University, Neuchâtel; [4]SO-PSY, Goumoens-la-Ville and [5]School of Nursing Sciences, La Source University of Applied Sciences and Arts, Lausanne, Switzerland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.303

Introduction: Recovery-oriented care requires a paradigm shift from a vulnerability to a protection model. However, protective factors and resources to recovery in urban milieus remain poorly understood. Whether material, emotional or social, the identification of those resources calls for user-led initiatives and a more situated understanding of environments, where those recovery trajectories occur.
Objectives: The Lausanne-based Urban Remediation program is a multi-stakeholder (service users, psychiatrists, geographers, community actors and public authorities) initiative, which aims to identify key elements of an 'urban recovery milieu for psychosis' and create such a milieu in the city of Lausanne (Switzerland). This talk describes the participatory methods used to create a strategy to foster recovery from psychosis in cities to better inform city's mental health plan and policies.
Methods: We implement a living lab approach aimed at real-world experimentation in four phases: (i) *exploration*, (ii) *co-creation*, (iii) *experimentation*, and (iv) *implementation*. During phase one, we've used participatory mapping, go-along interviews and photovoice for an *in-situ* engagement with 10 young patients to ensure a systematic understanding of obstacles and resources for recovery. For phase 2, qualitative analysis and collective workshops with the various stakeholders were used to co-elaborate relevant urban interventions and identify partners for further implementation.
Results: Introducing a Living Lab methodology to experiment the recovery-oriented strategy in a limited area in a real-world setting provides us with solutions, which can be further scaled up to inform the creation of a more inclusive city. Lessons learnt with early psychosis patients can benefit to the community as a whole, as high sensitivity of psychotic patients can teach us a great deal both regarding urban stressors and resources common to the general population.
Conclusions: Using real-world methodologies in cities allows to mobilize actors and resources beyond individual resilience to support recovery trajectories. Consistent transdisciplinary efforts are needed to involve all stakeholders (urban planners, mental health

plan developers and society at large) for effective user-based changes and implementation of sustainable solutions.

Optimizing Workplace Digital Mental Health Interventions: A Comprehensive Framework Based on Bayesian Meta-Analysis and Meta-Regression

N. Glozier[1]*, R. Morris[1], M. Deady[2], I. Choi[1], A. Milton[1] and E. Stratton[1]

[1]University of Sydney and [2]Black Dog Institute, Sydney, Australia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.304

Introduction: Digital mental health interventions have gained prominence as accessible and cost-effective solutions in workplace settings. However, our previous meta-analysis revealed a concerning trend: despite advancements in technology, the effectiveness of these interventions has not improved over time. This stagnation may be attributed to the significant and ongoing heterogeneity among interventions which indicates both variation in both sample and the intervention. We do not kow which theraputic approaches, design aspects or intervetnkion features enahnce efficacy.
Objectives: We use a Bayesian meta-regression of an unpdated systematic review to develop a comprehensive framework to guide the design, development, and evaluation of workplace digital mental health interventions. By addressing the variability in intervention approaches and design and leveraging evidence-based practices, this framework seeks to enhance the quality and effectiveness of digital solutions for employee mental health.
Methods: A systematic literature review was conducted to identify randomized controlled trials of employee based digital mental health interventions. Eligible studies were assessed based on specific criteria, including participant characteristics, intervention characteristics, and outcome measures. Data extraction and coding were performed, followed by a Bayesian meta-analysis approach. This method allowed for a more nuanced evaluation of the effectiveness of various intervention features and designs, accounting for uncertainty and prior knowledge in the field.
Results: The review identified 95 interventions involving approximately ˜25,000 participants. The Bayesian meta-analysis confirmed small positive effects in reducing mental ill-health symptoms. Both sample and intervention characteristics contributed to heterogeneity across studies. Stress management and mindfulness interventions, particularly those designed with input from mental health experts, demonstrated more effiacy than CBT based approaches. Several intervention features, such as videos, feedback scores, and reminder texts, were associated with positive mental health outcomes.
Conclusions: This review provides valuable insights into the optimal design and development of workplace digital mental health interventions. The identified framework and evidence-based practices offer guidance for developers to create effective interventions that address the heterogeneity within studies. Importantly, this framework has the potential to serve as a robust evidence base for app designers, enabling them to create more effective, personalised and engaging mental health applications.

Scrolling for Change: Using Instagram to Disseminate Evidence-Based Brief Video Interventions to Empower Childhood Trauma Survivors

S. Haim-Nachum[1,2]* and D. Amsalem[1]

[1]Department of Psychiatry, Columbia University, New York, United States and [2]School of Social Work, Tel Aviv University, Tel Aviv, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.305

Introduction: Childhood trauma (CT), especially experiences of abuse and/or neglect, is highly prevalent. Although CT significantly impacts mental health, those who experience it often avoid seeking treatment. Stigma –negative beliefs surrounding mental-health and trauma, is a primary obstacle to seeking care. We recently developed and demonstrated the efficacy of a brief video intervention designed to reduce stigma and increase openness to mental health care among CT survivors. This intervention was tested in a controlled environment (crowdsourcing platforms) to ensure that broader dissemination would cause no harm. Given the central role social media plays in the lives of youth, it is crucial to explore how it can be leveraged to deliver evidence-based mental health interventions effectively.
Objectives: The current study aimed to test the feasibility and acceptability of delivering this evidence-based intervention via social media, specifically Instagram. We hypothesized that the intervention would be both feasible (demonstrating high reach) and acceptable, generating better social media engagement metrics – such as higher link clicks and lower recruitment cost-per-click (CPC) rates, which indicate the intervention's cost-effectiveness, compared to the control video.
Methods: An eight-day Instagram campaign in February 2024 targeted U.S. youth aged 18-24. The campaign featured a 60-second personal story video, previously shown to reduce stigma among CT survivors, and a psycho-educational control video providing generic mental health facts, lacking social-contact elements. We assessed the campaign's total cost-effectiveness and key social media engagement metrics: Impressions (number of times the video was displayed), reach (number of distinct viewers), link clicks (engagement with treatment resources), and recruitment cost-per-click (CPC).
Results: The campaign generated 628,000 impressions, reached 209,000 Instagram users, and resulted in 4,015 link clicks, indicating its feasibility. The intervention video outperformed the control video in all measures, achieving 2,062 link clicks with a CPC of $0.79, compared to 1,953 link clicks and a CPC of $0.84 for the control group.
Conclusions: The findings suggest that Instagram can effectively disseminate cost-effective interventions, potentially improving attitudes about CT and encouraging youth to seek help.

Are online workers amenable to digital interventions? Results of a fully-remote nationwide trial of behavioral activation in 804 depressed adults in the United States

L. Lorenzo-Luaces[1]* and A. Peipert[1]

[1]Department of Psychological and Brain Sciences, Indiana University, Bloomington, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.306

Introduction: Online workers are individuals who participate in crowdsourced work. They experience a higher rate of internalizing symptoms than the general population, a phenomenon dubbed the "Turker blues." Three large trials of online single-session interventions (SSIs) failed to find statistical or clinically significant treatment effects in this population. Because these trials tested SSIs, it is unclear if online workers are unresponsive to SSIs in general or online interventions specifically. Moreover, participants in these studies were not selected based on their desire to learn skills online, raising the possibility that intervention effects would be present in treatment-seeking individuals.
Objectives: We conducted a nationwide, fully remote two-arm randomized (1:1) controlled trial to test the efficacy of a 4-week self-guided online behavioral activation treatment for depression in online workers in the United States (N=804). The intervention was designed as an extension of the Common Element Toolbox (COMET), an SSI previously found ineffective in online workers.
Methods: 804 online workers were randomized to COMET-BA or a waitlist control (WLC). Self-report measures of depression, anxiety, subjective well-being, behavioral activation, psychosocial function, and emotion regulation were collected weekly for 4 weeks, 1-week post-intervention, then at a 1-month follow-up.
Results: There was a significant time-by-treatment interaction during the intervention phase on the study, suggesting those in the COMET-BA arm improved significantly more than those in the WLC, with a small-medium effect on depression symptoms (SMD=-0.32; 95% CI: -0.47, -0.17). All but two outcomes, suppression and functioning, demonstrated significant improvement. Improvements were maintained during the 1-month follow-up period but did not grow during this period. Attrition was comparable between the treatments and the results were sensitive to missing data imputation.
Conclusions: COMET-BA may be effectively delivered as an unguided online intervention for depression in online workers. Crucially, intervention effects were evident after the second iBA session, suggesting that SSIs may not be effective in adult online workers.

Socioeconomic inequalities on unmet needs for mental health care: a cross-section analysis in European Union countries

J. V. Santos[1,2,3]* and V. Pinheiro[4]

[1]University of Porto; [2]RISE-Health / CINTESIS; [3]ULS Santo António and [4]University of Porto / ULS Matosinhos, Porto, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.307

Introduction: Mental health disorders are a leading cause of disability in European Union countries. Previous evidence highlighted the role of socioeconomic inequalities on unmet mental health care needs, varying by income or education. Being both reducing inequalities' gaps and mental health promotion current goals of European Union (EU), it is essential to understand the differences between EU countries and the role of socioeconomic factors on this.
Objectives: The study aims to assess the socioeconomic inequalities on unmet needs for mental health care in EU countries in 2019.
Methods: This was a cross-sectional study using data from the 2019 European Health Interview Survey across 26 EU countries. The main outcome considered was the proportion of self-reported unmet needs for mental health care due to financial reasons. Inequalities for income, education and degree of urbanization were assessed by calculating the rural-city, primary-tertiary education and lowest-highest income quintiles, respectively.
Results: The proportion of self-reported unmet need for mental health care in 2019 ranged between 1.1% (Romania) and 27.8% (Portugal), with a median of 3.6%. Regarding income inequality, all countries except Hungary (ratio=0.88) showed highest share of unmet need among inhabitants with the lowest income quintile. The country with the highest inequality was Greece with a ratio of 23.8. Regarding education inequality, 15 out of 26 countries showed that less educated inhabitants had highest unmet needs of mental health care, with values ranging from 0.5 in the Netherlands and 7.2 in Bulgaria. As for degree of urbanization, rurality showed lowest unmet needs for 21 out of 26 countries, with the highest ratio being 2 in Romania.
Conclusions: The study highlights significant and wide socioeconomic (income, education, and urbanization) inequalities in unmet mental health care needs across EU countries.
While income inequality plays a similar role across EU countries with the poorer quintile showing higher unmet needs due to financial reasons, EU is divided on the role that education plays. On the opposite side, there is also a tendency across the EU for rural areas showing lower unmet needs for mental health care. Policymakers should prioritize strategies to ensure financial access to mental health services, as well as promoting mental health literacy and improve service availability for vulnerable populations.

The rise of online gambling addiction: A mental health challenge

R. M. Cabral[1]*, C. Cunha[1], P. Pires[1], I. Santos[1], F. Cunha[1], A. Oliveira[1], N. Gil[1] and F. Coias[2]

[1]Psychiatry, ULS-Viseu Dão Lafões, Viseu and [2]Family Medicine, ULS-Alentejo Central, Evora, Portugal

doi: 10.1192/j.eurpsy.2025.308

Introduction: Gambling disorder is a rising concern among young adults, highlighting the need for effective screening to offer appropriate support and intervention.
Objectives: This study aims to characterize gambling disorder among young adults (ages 18-25) in Portugal.
Methods: A quantitative cross-sectional study was conducted using a self-administered online questionnaire completed by young adults.
Results: This study included a population of 554 participants, 166 of whom were gamblers. Among the gamblers, the prevalence was as follows: 63% did not show signs of pathological gambling, while the remaining participants exhibited gambling addiction at varying levels: 25% mild, 9% moderate, and 3% severe. The typical profile of a gambler was identified as a male university student with an average age of 23.5 years, of a middle economic status and residing in an urban area. The preferred types of gambling were sports betting and online casino games. Most online gamblers had previously engaged in offline gambling at the age of M=19.25. The primary attractions of online gambling for these individuals were accessibility, the variety of games, and the potential for economic gains. The main encouragements to gamble online were friend´s influence and online advertising. No significant differences were observed in depression (PHQ-9) and anxiety scores (GAD-7) between gamblers and non-gamblers ($p > 0.05$). However, among gamblers, a strong positive correlation was found between higher levels of addiction (assessed by DSM-V gambling disorder criteria) and both depression and anxiety scores ($r = 0.732$, $r = 0.681$; $p < 0.01$). Furthermore, severe gambling cases were associated with a higher prevalence of prior formal diagnoses of psychiatric disorders, such as ADHD, anxiety, and depression, although this association was not statistically significant ($p > 0.05$). All gamblers showed a higher prevalence of substance abuse ($p < 0.01$). However, this trend did not extend to alcohol consumption ($p > 0.05$). The Jacobs Dissociative Experiences Scale was used to assess the presence of dissociative symptoms in relation to the severity of gambling addiction, revealing a strong positive correlation ($r = 0.721$; $p < 0.01$). Gamblers reported negative impacts on their family and romantical relationships. In contrast, they did not perceive their gambling behavior as having an adverse effect on their friendships or work performance. The majority (71.4%) of high-severity gamblers did not seek professional help and were not receiving any psychopharmacological therapy.
Conclusions: This study features the critical need for effective screening and intervention strategies for gambling disorder among young adults, given its correlation with mental health disorders and substance abuse. Addressing these challenges is essential for enhancing support and improving outcomes for individuals with gambling disorder.

Seasonality and weather influence on mixed episodes of bipolar disorder

F. Cunha[1]*, E. Almeida[1], N. Castro[1], J. Abreu[1], R. Cabral[1] and D. Teixeira[2]

[1]ULS Viseu Dão-Lafões, Viseu and [2]ULS Cova da Beira, Covilhã, Portugal

doi: 10.1192/j.eurpsy.2025.309

Introduction: Seasonal patterns in bipolar disorder episodes, particularly manic episodes, have been widely studied, revealing a peak in early spring and a decline in late fall. However, less attention has been given to the seasonal variation of mixed states. Mixed episodes, a subtype of bipolar disorder, are characterized by both manic and depressive symptoms. Recent studies have suggested that mixed episodes may follow a different seasonal pattern compared to pure manic episodes, peaking in late summer. Understanding this seasonality can offer valuable insights into the timing and management of hospital admissions for bipolar disorder. In this study, we conducted a retrospective analysis of hospital admissions for bipolar disorder, evaluating the influence of meteorological factors on the frequency of admissions, particularly for mixed episodes.
Objectives: This study aims to analyze the prevalence of hospital admissions due to bipolar disorder at the Psychiatry Service of ULS-VDL during 2021 and 2022, with a particular focus on mixed episodes. Additionally, it seeks to explore the relationship between meteorological factors, such as temperature and cloud cover, and the frequency of admissions, identifying any seasonal patterns associated with bipolar episodes. This analysis aims to explore the potential link between environmental changes, such as temperature and cloud cover, and the occurrence of mixed states in bipolar disorder.
Methods: A retrospective analysis was conducted of hospital admissions for bipolar disorder between 2021 and 2022 (n=71) at the Psychiatry Service of ULS-VDL. Monthly averages of meteorological data (temperature, precipitation, cloud cover, and solar radiation) were obtained from a local weather station. Poisson regression was used to assess the relationship between monthly admissions and meteorological variables.
Results: Of the 71 total episodes, 16 were mixed episodes of bipolar disorder. The results showed a statistically significant association between decreased temperature (IRR=0.843, 95% CI [1.568-0.118], p=0.023) and increased cloud cover (IRR=0.162, 95% CI [0.023-0.302], p=0.023), compared to the previous month, and an increase in admissions for mixed episodes.
Conclusions: The findings of this study indicate a significant association between decreases in temperature and increases in cloud cover with higher rates of hospital admissions for mixed episodes of bipolar disorder. These results highlight the potential influence of meteorological factors on the seasonality of mixed episodes. Further research is needed to confirm these patterns

and to explore their implications for the management and prevention of bipolar disorder hospitalizations.
Note: We intend to increase the number of years included and episodes.

Simultaneous blockade of α1b-adrenergic and 5HT2A-serotonergic receptors for the treatment of alcohol use disorder: a randomized, placebo-controlled proof-of-concept phase-2 trial

J. Guiraud[1,2]

[1]Psychiatry, Amsterdam UMC, University of Amsterdam, Amsterdam, Netherlands and [2]Vergio, Clichy, France
doi: 10.1192/j.eurpsy.2025.310

Introduction: Alcohol use disorder (AUD) is associated with increased dopaminergic activity, and evidence suggests that α1b-adrenergic and 5HT2A serotonergic receptors play critical roles in modulating dopamine-mediated behavioral responses. Preclinical studies indicated that simultaneous blockade of these receptors with prazosin (α1b blocker) and cyproheptadine (5HT2A blocker) can reduce alcohol preference. This phase 2 clinical study aimed to evaluate the efficacy and safety of this combination in reducing alcohol consumption among patients with severe AUD.
Objectives: The primary objective of the study was to assess the efficacy and safety of a combination of prazosin extended-release (ER) and cyproheptadine in reducing total alcohol consumption (TAC) in patients with severe AUD.
Methods: This was a phase 2, double-blind, parallel-group, placebo-controlled, randomized clinical trial conducted across 32 addiction treatment centers in France. A total of 154 participants (108 men and 46 women) with severe AUD were randomly assigned to one of three treatment groups for 3 months: 1) low-dose group (LDG) with 8 mg cyproheptadine and 5 mg prazosin ER daily, 2) high-dose group (HDG) with 12 mg cyproheptadine and 10 mg prazosin ER daily, or 3) placebo group (PG). The primary outcome was the change in TAC from baseline to Month 3. Secondary outcomes included changes in heavy drinking days, abstinence days, Obsessive Compulsive Drinking Scale (OCDS), and Beck Depression Inventory (BDI) scores. Safety was assessed through adverse events (AEs), sedation, and orthostatic hypotension (OH).
Results: A significant main treatment effect in TAC change was observed in the intent-to-treat (ITT) population (p=0.039). Compared to the placebo group, the HDG showed a greater reduction in TAC from baseline to Month 3 (-23.6 g/day, p=0.016, Cohen's d=-0.44), while the LDG also showed a reduction (-18.4 g/day, p=0.048). In the very high-risk drinking level subgroup (>100g/day of pure alcohol for men and >60g/day for women), the HDG showed a reduction of -29.8 g/day compared to the PG (p=0.031, d=-0.51). A significant dose-response relationship (p=0.027) was observed. Both low and high doses were well-tolerated, with AEs predominantly mild or moderate. No serious adverse events were reported in the HDG, and OH incidence was comparable across groups.
Conclusions: The combination of prazosin and cyproheptadine showed efficacy in reducing alcohol consumption in individuals with severe AUD, with a larger effect observed in the high-dose group. Both doses were well-tolerated, with a safety profile comparable to placebo. These findings suggest that the prazosin-cyproheptadine combination may be a promising treatment option for severe AUD and warrant further investigation in phase 3 trials.

Patient-reported measures in substance use disorder treatment services: a scoping review and preliminary results from a multicenter study

C. Migchels[1]*, W. van den Brink[2], A. Zerrouk[3], W. Vanderplasschen[3] and C. L. Crunelle[1]

[1]Psychiatry, Vrije Universiteit Brussel, Universitair Ziekenhuis Brussel, Brussels, Belgium; [2]Psychiatry, Amsterdam University Medical Centers, University of Amsterdam, Amsterdam, Netherlands and [3]Special Needs Education, Universiteit Gent, Gent, Belgium
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.311

Introduction: Patient-centered treatment and care is a key quality standard within substance use disorder (SUD) treatment services. Patient-Reported Outcome and Experience Measures (PROMs and PREMs) allow us to collect direct feedback from patients on how they perceive health outcomes and quality of care in a systematic way.
Objectives: To identify current practices regarding the use of PROMs and PREMs in clinical practice in SUD treatment services and to develop an electronic self-report tool for routine assessment of PROMs and PREMs in SUD treatment services in Belgium.
Methods: We present results from a scoping review, identifying studies reporting on the use and routine implementation of PROMs and PREMs in SUD services. Additionally, preliminary results from a naturalistic longitudinal multicenter study assessing self-reported sociodemographic characteristics, clinical factors, PROMs, and PREMs in N=189 adults who recently started treatment for SUD in various treatment modalities are presented: the OMER-BE study (Outcome Measurement and Evaluation as a Routine practice in alcohol and other drug services in Belgium).
Results: There is an increasing use of patient-reported measures in SUD services. However, there is large variation in the patient-reported measures that are used, how they are developed, and how and when patient-reported data are collected. The most important barriers and facilitators to the implementation of PROMs and PREMs in clinical practice include burden to and involvement of staff, and leadership and technical support. Alcohol and cocaine were the most commonly used substances among participants of the OMER-BE study, with 59.7% of participants reporting polysubstance use. The 45-, 90-, and 180-day follow-up assessments were completed by 64%, 59% and 54% of participants respectively. At 180-day follow-up, 56% of respondents were still in treatment for SUD.
Conclusions: Guidance is needed to support clinicians in selecting and implementing valid, meaningful, and comparable patient-

reported measures to understand and benefit from the impact that PROMs and PREMs can have on treatment quality and outcome. The OMER-BE study provides an example of the insights that can be gained into patient needs through the use of an electronic self-report tool assessing PROMs and PREMs.

Clinical characteristics associated with future clozapine treatment among patients with bipolar disorder: A nationwide register-based study of 29,696 patients

E. Salagre[1,2*], C. Rohde[1,2] and S. D. Østergaard[1,2]

[1]Department of Affective Disorders, Aarhus University Hospital and [2]Department of Clinical Medicine, Aarhus University, Aarhus, Denmark

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.312

Introduction: Despite the number of medications considered as effective in the treatment of bipolar disorder (BD), incomplete response to treatment is very prevalent (Perlis *et al.* Am J Psychiatry 2006;163(2):217-24). Existing evidence supports the effectiveness of clozapine for treatment-resistant BD (TRBD) with clinical guidelines recommending clozapine as a third-line treatment (Yatham *et al.* Bipolar Disord. 2018;20(2):97-170). There is evidence to support that a shorter delay before clozapine initiation is associated with a better response to this treatment (Griffiths *et al.* Psychol. Med. 2021;51(3):376-86).

Objectives: This study aimed to identify clinical and sociodemographic characteristics at the time of the first bipolar diagnosis associated with future clozapine treatment.

Methods: We performed a population-based cohort study using nationwide data from Danish registries to investigate factors associated with initiation of clozapine treatment in incident BD. Cox proportional hazard regression analyses were used to investigate associations between patients' characteristics at the time of the diagnosis of BD and a subsequent redemption of a prescription for clozapine, yielding hazard rate ratios (HRRs).

Results: We identified a total of 29,696 patients registered with their first (incident) ICD-10 diagnosis of BD between 1999 and 2019, of whom 102 (0.3%) received clozapine treatment during follow-up. The median age at the first prescription of clozapine was 48.6 years (25-75 percentile: 37.7-59.9). The multivariable Cox proportional hazards regression model showed that a prior diagnosis of psychotic disorder (other than schizophrenia or schizoaffective disorder) (HR: 2.10; CI: 1.13-3.93), having had three (HRR: 2.91; CI: 1.23-6.87), four (HRR: 2.89; CI: 1.15-7.24) or five or more (HRR: 3.17; CI: 1.19-8.44) previous psychopharmacological treatments prior to the diagnosis of BD, and being outside the labour force (HRR: 2.58; CI: 1.42-4.66) were positively associated with clozapine treatment after controlling for the remaining variables.

Conclusions: The results of this study suggest that there are clinical characteristics associated with subsequent clozapine treatment already at the time of diagnosis of BD. These findings may guide targeted interventions, such as an earlier initiation of clozapine treatment.

Relationship between daily rhythms and verbal memory in individuals with Bipolar Disorder

K. T. Svee[1*], A. Engum[1], G. Morken[2] and T. I. Hansen[3]

[1]Division of Mental Healthcare, St. Olavs Hospital; [2]Department of Mental Health and [3]Department of Neuromedicine and Movement Science, Norwegian University of Science and Technology, Trondheim, Norway

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.313

Introduction: Cognitive function, particularly verbal memory, is often compromised in Bipolar Disorder (BD). While studying risk factors for cognitive deficits has not identified causal factors, focusing on protective factors that support verbal memory can help tailor interventions for individuals with BD.

Objectives: Investigate associations between daily rhythms and verbal memory in people with BD in full or partial remission.

Methods: This is a cross-sectional study. Participants were included if their Montgomery Asberg Depression Rating Scale (MADRS) score was ≤16 and Young Mania Rating Scale (YMRS) score was ≤8. Daily rhythms were assessed by self-report using the BRIAN scale, as was chronotype. Regularity and intensity of physical activity were measured with actigraphy, with devices worn on the wrist for up to ten days. Variables of interest included mean time per day in moderate to vigorous physical activity (MVPA), intensity and timing of the most active five hours per day (M5), and total intensity per 24 hours over the assessment period. Cognitive function was assessed using a validated, self-administered, web-based test platform for Norwegian-speaking participants, which included a verbal memory test. Actigraphy data were processed using specialized software to extract relevant metrics. Correlational analysis was conducted to evaluate the relationships between daily rhythms and verbal memory.

Results: A total of 87 participants were included, comprising 30 men and 57 women, aged between 18 and 64 years. Among them, 57 had bipolar disorder type 2, and 30 had bipolar disorder type 1. The analysis revealed a significant positive correlation between verbal learning and the timing of the most active five hours, with better verbal learning observed for M5 timing later in the day. There was also a moderate positive correlation between better delayed verbal recall and the amount of time spent in moderate to vigorous physical activity.
Conclusions: Our findings suggest that modifiable factors, such as later timing of the most active five hours and amount of time spent in moderate to vigorous physical activity, are associated with better verbal learning and memory in individuals with bipolar disorder. These insights could inform interventions aimed at improving cognitive outcomes in this population.

Antipsychotic Dosage and Frequency of Manic Episodes as Predictors of Metabolic Syndrome in Bipolar Disorder: A One-Year Follow-Up

R. Tekdemir[1]*, M. T. Ergün[1] and H. A. Güler[2]
[1]Psychiatry and [2]Child and Adolescent Psychiatry, Selcuk University Faculty of Medicine, Konya, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.314

Introduction: Metabolic syndrome (MetS) is notably prevalent among individuals with bipolar disorder (BD). Despite numerous studies indicating an increasing MetS prevalence in this group over time, comprehensive investigations of associated risk factors remain limited.
Objectives: This study aims to assess the prevalence and 1-year changes in MetS among BD patients. It also seeks to identify baseline clinical features that could predict the development of MetS during follow-up.
Methods: The study included euthymic BD type 1 patients consecutively admitted between July 2023 and July 2024. MetS was diagnosed uaccording to NCEP ATP-III criteria at baseline and after one year. Patients without MetS at baseline were analyzed to evaluate the association between initial clinical characteristics and MetS presence at follow-up through logistic regression.
Results: A total of 98 patients completed the baseline and follow-up assessments. The prevalence of MetS significantly increased from 29.6% to 51.0% over the 1-year naturalistic follow-up. Initially, there were no significant differences between the groups with and without MetS regarding demographics, illness characteristics, treatment types, comorbidities, and chlorpromazine equivalent dose. By the end of the follow-up period, 29 new MetS cases were diagnosed after excluding those initially identified. This group exhibited higher numbers of total episodes, more manic episodes, and greater hospitalization rates (p = 0.04,-2.067; p = 0.03, -2.193; p = 0.03, -3.207), with no significant differences in other demographic or clinical variables.In the logistic regression analysis, which controlled for age, gender, number of depressive episodes, and the use of lithium and valproate, the equivalent chlorpromazine dose (p = 0.04, OR: 1.003) emerged as a significant predictor of metabolic syndrome, while the number of manic or hypomanic episodes demonstrated a trend towards significance (p = 0.05).
Conclusions: In conclusion, this study shows that the prevalence of MetS in patients with BD type-1 in Turkey increased from 29.6% to 51.0% over one year. Increased numbers of manic episodes and higher chlorpromazine doses were linked to the development of MetS. This underscores the importance of monitoring metabolic health, especially in patients with frequent manic episodes or high antipsychotic doses.

The influence of methamphetamine utilization patterns and adverse childhood experiences on Methamphetamine Use Disorder and Methamphetamine-Induced Psychosis

N. A. Tran[1]* and R. Kalayasiri[1]
[1]Department of Psychiatry, Chulalongkorn University, Bangkok, Thailand
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.315

Introduction: Methamphetamine (MA) is one of the most addictive drugs globally. Among its harmful consequences, methamphetamine use disorder (MUD) and methamphetamine-induced psychosis (MAP) are prevalent and increase the burden of mental health worldwide. Recent studies highlighted the relationship of the disorders and various factors including patterns of MA consumption and adverse childhood experiences (ACEs). Understanding the association between these factors and MUD and MAP is essential for advancing our knowledge and improving healthcare for our patients.
Objectives: To investigate the association of MA use patterns, ACEs and the development of MUD and MAP.
Methods: This study analyzed data from a survey using the Thai-MIND questionnaire (September 2023 – June 2024). We collected participants' socio-demographic details (including gender, age, income, employment, marital status, education), mental health history, other substances use, MA use patterns, ACEs, psychotic symptoms and their onset. The diagnosis of MUD and MAP were based on DSM-5 criteria. Univariate logistic regression was employed to examine the relationships, adjusting for socio-demographics and mental health history for MUD models, and adding other substances use and MUD diagnosis for MAP models.
Results: In this study of 2,524 participants, 1,987 (78.72%) met the criteria for MUD, and 876 (34.71%) met the criteria for MAP. The use of yaba (MA or speed pill) reduced the risk of MAP compared to ice (crystalline MA)(OR = 0.32 [0.12 – 0.85]) while combining two types of MA raised the risk of MAP compared to ice alone (OR = 1.96 [1.37 – 2.81]). For MUD, more frequent MA use, compared to monthly or less, increased the risk with OR = 1.81 [1.34 – 2.43] (2-4 times/month), 2.27 [1.58 – 3.27] (2-3 times/week), and 4.00 [2.87 – 5.59] (4 or more times/week). Similarly, for MAP, using MA 2-3 times/week raised the risk (OR = 1.59 [1.14 – 2.22]), and using it

more than 4 times/week further increased the risk (OR = 2.16 [1.62 – 2.87]). Additionally, MA injection significantly heightened the risk of MUD (OR = 6.29 [3.28 – 12.04]). Emotional abuse (OR = 1.84 [1.36 – 2.47]) and physical abuse (OR = 1.71 [1.29 – 2.27]) were linked to a higher risk of developing MUD. In addition, physical neglect (OR = 1.29 [1.02 – 1.65]), emotional neglect (OR = 1.47 [1.13 – 1.90]), and sexual abuse (OR = 1.46 [1.05 – 2.03]) were associated with an increased risk of MAP. The total number of ACEs also increased the risk of both MUD (OR = 1.28 [1.17 – 1.40]) and MAP (OR = 1.14 [1.05 – 1.24]).
Conclusions: The study demonstrates that MA use patterns and adverse childhood experiences significantly impact the risk of developing MA use disorder and MA-induced psychosis.

doi: 10.1192/j.eurpsy.2025.316

Introduction: Some individuals with chronic pain using opioid analgesics may unknowingly experience mood improvement, which can lead to compulsive opioid use. To address this issue, the DOLMEN program was developed, involving a multidisciplinary team of clinical psychologists, psychiatrists, pain specialists, nurses, pharmacists, and geneticists for a comprehensive treatment approach.
Objectives: Our objective was to describe the DOLMEN program and assess its effectiveness in improving emotional pain, psychiatric symptoms, functioning, quality of life, and pain management. The program also aimed to prevent medication errors through pharmacological guidance. We investigated genetic biomarkers related to clinical outcomes and evaluated patient satisfaction with the program.
Methods: We implemented a multidisciplinary pilot program and conducted an observational, unicentric, longitudinal, and ambispective study to evaluate its outcomes. The study included patients with chronic pain on high off-label opioid doses, those with mental disorders treated with opioids, and patients with pain refractory to standard treatments. Data were collected on psychiatric symptoms, substance use, CYP2D6, CYP2C19, and OPRM1 gene polymorphisms, and pharmacist interventions. To assess the intervention's impact, a paired test analyzed changes in psychiatric measures and pain levels using the Visual Analog Scale (VAS) after structured psychoeducational sessions. A linear-by-linear association chi-square test examined associations between genetic polymorphisms and questionnaire results.
Results: The sample consisted of 90 patients, the majority of whom were women (78.0%), with a mean age of 53.1 years. Among the participants, 23.0% exhibited problematic opioid use.
Significant improvements were observed in several clinical measures. The average Clinical Global Impression score improved from 3.7 to 2.58 (p=0.003), while the State-Trait Anxiety Inventory scores for state anxiety and trait anxiety decreased from 38.8 to 34.9 (p=0.0027) and from 40.1 to 35.8 (p<0.0001), respectively. The Beck Depression Inventory-II scores also showed a notable reduction from 33.1 to 27.8 (p<0.0001). Although improvements were seen in the EQ-5D-5L (from 41.1 to 50.2) and the EEAG (from 65.8 to 71.8), these changes were not statistically significant (p>0.05). Pain experience, as measured by the Visual Analog Scale, showed a reduction from 7.1 to 6.6 (p=0.0106). An association was identified between the OPRM1 polymorphism and the degree of problematic opioid use, as well as between the CYP2C19 genotype and the presence of depression (p<0.05). Additionally, pharmacists provided 64 recommendations to patients to prevent medication errors throughout the program.
Conclusions: The DOLMEN program demonstrated preliminary effectiveness in managing patients with chronic and emotional pain, as well as problematic opioid use.

doi: 10.1192/j.eurpsy.2025.317

Introduction: Functional neurological disorders (FND) are defined as neurological symptoms that are inconsistent and incongruent with classic neurological disorders. Over the past two decades, an interest in the potential underlying mechanisms of these disorders has occurred and a new pathophysiological framework based on current neurobiological theories about global brain function such as the predictive coding theory has emerged. Within this framework, abnormal or erroneous beliefs about symptoms, mediated by attention, are hypothesized to modulate perception and movements, ultimately leading to FND. Previous studies have evaluated cognitive biases such as the jumping to conclusion reasoning style in patients with functional movement disorders (FMD) and it has been suggested that they may play a role in symptoms production. In this study, we evaluated the behavior of patients with FMD when confronted with evidence that contradicts their beliefs through the "Bias Against Disconfirmatory Evidence" (BADE) and their tendency to accept implausible interpretations through the "Liberal Acceptance Bias" (LA).

Objectives: To evaluate whether patients with FMD have greater difficulty integrating information based on disconfirming evidence than the general population.
Methods: Observational case-control study in which the presence of BADE and LA biases were assessed in a sample matched by sex and age using Woodward's BADE task. Clinical and demographic characteristics of the participants were recorded (such as "Mini Mental State Examination" (MMSE) or "Peters et al. Delusions Inventory" (PDI -21), level of education, employment situation and marital status and cohabitation situation). The BADE test analyses the scores that the patient provides at 3 points in time on the plausibility of 24 scenarios after increasing the information received.
Results: Twenty patients (median age 50.5 years, 75% female) and twenty people from the control group (median age 52.50 years, 75% female) were included. No differences were found on demographic features, MMSE or PDI -21 scores. When compared to healthy controls, FMD patients scored significantly lower in BADE (median 3.35, p=0.03) and significantly higher in LA (median 3.08, p=0.017). Also, when the maximum information was provided, patients scored significantly higher in implausible situations (p=0.01) and lower in true situations (p=0.02) than the control group.

Median	3,08	2,29	**0,017** *

Conclusions: Patients with FMD have greater difficulty in modifying their beliefs when confronted with disconfirming evidence and a greater tendency to accept less plausible options. These cognitive biases, among other factors, may facilitate the adoption of fixed beliefs, regardless of their plausibility, early and with little evidence. Our results may also explain why some patients with FMD remain with erroneous beliefs despite the explanation of the diagnosis.

Theoretical and Empirical Basis of Psychogenic Aging

M. Faria[1]
[1]Cognition and Brain Sciences Unit, University of Cambridge, Cambridge, United Kingdom
doi: 10.1192/j.eurpsy.2025.318

Introduction: Psychogenic aging, an emerging field in biogerontology, seeks to integrate psychological factors into the biological framework of aging. Traditional models of aging emphasize molecular and cellular mechanisms, often overlooking the significant role of psychological well-being. Our studies show that psychosocial factors influence biological age similarly to physical health conditions. Psychogenic aging is a novel phenomenon that addresses this gap by providing a holistic understanding of the aging process that encompasses both biological and psychological components.
Objectives: The primary objective of this research is to explore the relationship between psychological factors and biological aging. Specifically, it seeks to quantify the impact of psychosocial stressors and well-being on biological age and compare these effects with established biological markers of aging. This study also aims to position psychogenic aging within the established Hallmarks of Aging framework.
Methods: Data from the China Health and Retirement Longitudinal Study (CHARLS), including 16 blood biomarkers and psychological well-being indicators for over 11,000 adults, were used to train a deep neural network (DNN) to predict biological age.Psychosocial factors such as happiness and loneliness were regressed against biological age using elastic net regression to quantify their effects.
Additional findings from a non-systematic review on stress and aging were used to frame the psychogenic aging model within the Hallmarks of Aging framework by Lopez-Otín *et al.* 2013 Cell.
Results: Galkin *et al.* Aging 2022 developed a deep-learning aging clock using blood test data to assess the influence of psychological factors on biological aging. The results show that negative psychological factors, such as loneliness and unhappiness, can accelerate

biological age by 1.65 years, surpassing the effect of smoking, which contributes an additional 1.25 years. These findings highlight the substantial impact of mental well-being on biological age, comparable to serious health conditions like stroke and lung disease. Faria *et al.* Trans Psych 2024 developed a theoretical framework from which to conceptualize the mechanisms and mediators behind these psychogenic aging effects with the latest high-throughput methods.

Image 1:

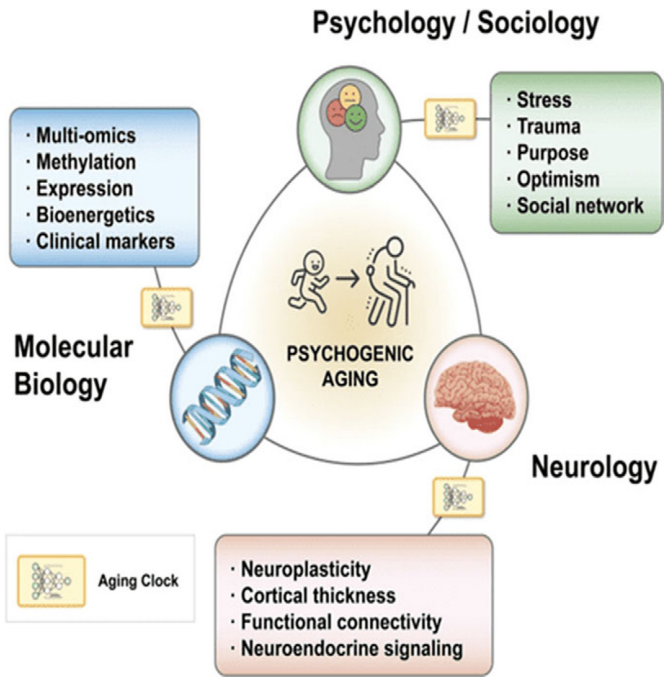

Image 2:

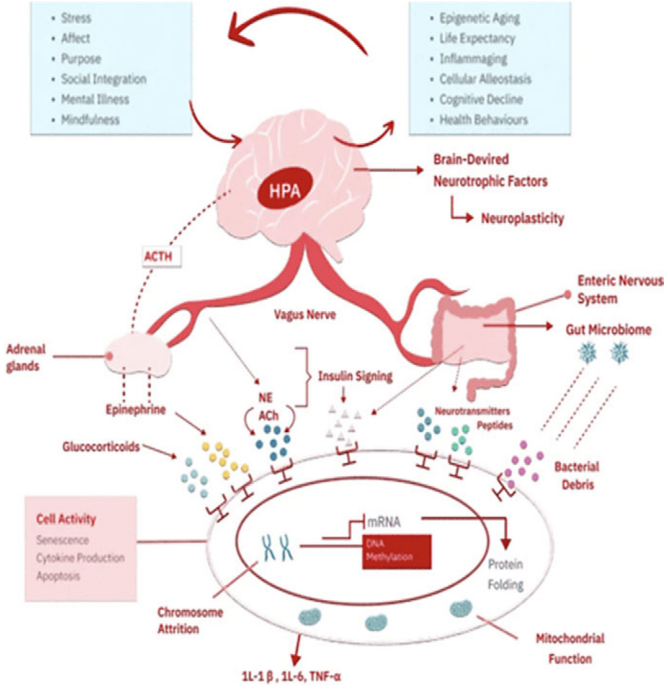

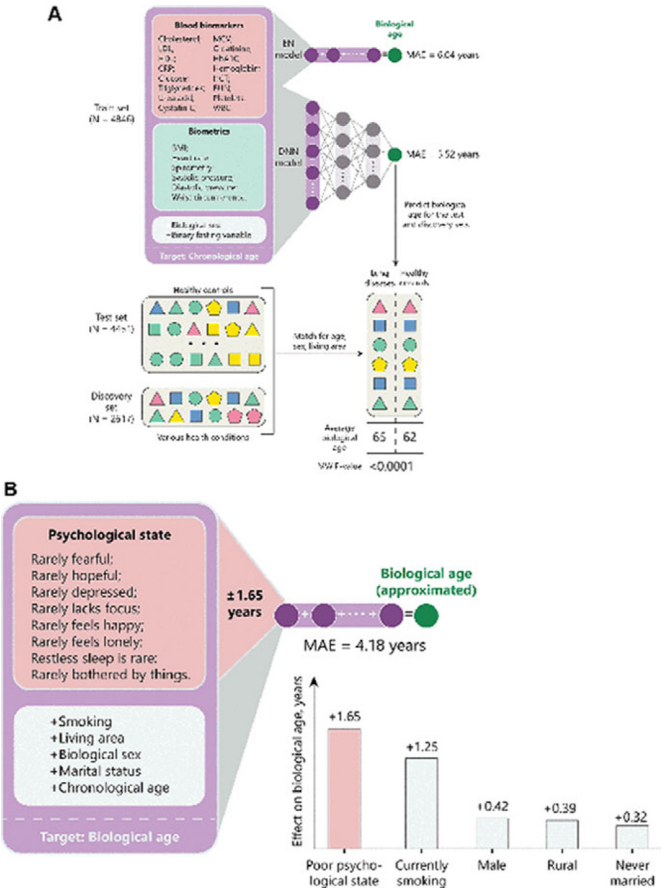

Image 3:

Conclusions: The integration of psychogenic aging into the Hallmarks of Aging framework represents one of the most significant advancement in our understanding of the aging process. Psychological stressors and resilience should be recognized as fundamental contributors to aging, akin to molecular and cellular processes. By addressing both the biological and psychological dimensions of aging, this interdisciplinary approach offers novel opportunities for anti-aging therapies and interventions. Future research should focus on validating these findings across diverse populations and exploring the mechanistic pathways linking psychological health to biological aging.

Using an innovative web-based task management application to improve medical handovers at an in-patient psychiatric hospital

H. Hamilton[1]* and K. Laffan[1]

[1]Psychiatry, South London and Maudsley NHS Trust, London, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.319

Introduction: Safe and effective handovers are crucial for patient safety in psychiatric hospitals and a digital record helps to prevent information loss and allow auditing. Trainees at our institution raised concerns about the lack of a reliable, traceable digital record for out-of-hours handovers. The pre-existing system of handwritten notes and emails was error-prone, cumbersome and untraceable. Therefore, a more efficient digital system was needed to match the demands of a busy in-patient psychiatric hospital.
Objectives: To improve the safety and quality of medical handovers in our hospital.
Methods: A baseline survey was sent to resident doctors at The Maudsley Hospital, London, to gather feedback on handover practices. The Microsoft Planner application within Teams was introduced, providing a secure, live digital handover record accessible with two-factor authentication. It allows multiple users to edit tasks simultaneously and tracks all updates with clinician specific time stamps. Changes were communicated and feedback gathered through monthly meetings, emails, and encrypted messaging apps. After 12 weeks, we sent a follow-up survey and made further adjustments based on the feedback.
Results: Nine doctors responded to the baseline survey, giving an average score of 2.5 out of 5 for quality and 2.4 out of 5 for safety. Forty-six percent struggled to prioritize tasks during on-call shifts, 54.6% found it hard to track task progress, and 18.2% reported frequent task delays or omissions. After the changes, nine doctors responded with improved scores of 4.6 out of 5 for quality and 4.2 out of 5 for safety. Seventy-eight percent rarely had difficulty prioritizing tasks, 66.7% found it easy to track progress, and 87.5% reported that tasks were rarely or never missed. Feedback highlighted that use of the platform varied amongst clinicians and access issues for emergency locum doctors, leading to the creation of a trust-wide protocol to standardise the use of this technology and respond to access issues.
Conclusions: A web-based task management platform was introduced in a large in-patient psychiatric hospital with significant improvements seen in clinician-rated quality and safety of medical handovers. This application is now commonly used across South London and Maudsley NHS Trust, the largest mental health trust in the United Kingdom. Over 450 NHS organizations have access to the Microsoft 365 and could therefore use this innovative technology to improve their clinical handovers. Given Microsoft's global use, this could very likely be used throughout European mental health organisations.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.320

Introduction: Lithium is used as a first-line treatment in perinatal bipolar disorder. Lithium is almost exclusively renal eliminated without undergoing metabolization. Renal changes associated with pregnancy are responsible for alterations in lithium pharmacokinetics that may impact lithium efficacy and toxicity in mother. Characterization of the trajectory of lithium disposition during the perinatal period (previous year of pregnancy, pregnancy and first year postpartum) is necessary to monitoring and dose adjustments to prevent bipolar symptom recurrence while minimizing adverse effects.
Objectives: To characterize the disposition of lithium during the perinatal period ant to evaluate whether changes in serum lithium concentration are consistent with changes in renal function (creatinine).
Methods: Women treated with lithium carbonate and referred to the perinatal psychiatry out-patient clinic of a single tertiary university hospital (November 2006 -December 2018), were evaluated for eligibility to participate in this retrospective observational cohort study (HCB/2020/1305). The basis of this study was all samples analysed in the same laboratory for lithium during perinatal period obtained at steady-state and predose. Serum creatinine concentrations measurements were also extracted. Lithium concentrations were determined by means of an AVL 9180 electrolyte analyzer based on the ion- selective electrode (ISE) measurement principle. Detection limit (LoD) was 0.1 mEq/L and limit of quantification (LoQ) 0.2 mEq/L. Serum creatinine concentration was determined by molecular absorption spectrometry. Detection limit (LoD) was 0.10 mg/dL, and the limit of quantification (LoQ) was 0.15 mg/dL Linear mixed models were used to analyze lithium and creatinine serum concentrations.Time points extractions and lithium dose were included as fixed effects, while the individual mother was included as a random effect to account for repeated measurements.
Results: In total, 1260 lithium and 1174 creatinine serum concentration measurements from 109 pregnancies of 95 women were available. Dose-ajusted serum lithium concentrations (C/D ratio) decreased and average of 23.9% and 27.6% during the first and second trimesters respectively, increased slightly in the third

trimester but remained 16.9 % below the prconception time (reference period) and increased postpartum 11% . Serum creatinine concentration evidenced a similar longitudinal pattern during pregnancy (decreased 20%, 26.1% and 22.3% in first, second and third trimester respectively) and also decreased postpartum 4.3%.
Conclusions: We recommend monitoring lithium and creatinine serum concentration once every 4 weeks until 34 weeks of pregnancy, then weekly until delivery, followed in postpartum at day 2 ±1, (bi-)weekly during the first month, monthly until 6 months postpartum and then every 3-4 months to ensure adequate lithium dosing.

Supporting mental health of healthcare staff: health economics evaluation of costs and clinical outcomes of a specialised clinic for healthcare workers

M. Kaser[1,2*], K. Puri Sudhir[3], A. Wagner[3], S. Said[1], T. Karadaki[1], C. Walsh[4] and R. Cameron[3]

[1]Staff Mental Health Service, Cambridgeshire and Peterborough NHS Foundation Trust; [2]Department of Psychiatry, University of Cambridge, Cambridge; [3]Health Economics Group, University of East Anglia, Norwich and [4]Psychological Medicine, Cambridgeshire and Peterborough NHS Foundation Trust, Cambridge, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.321

Introduction: Healthcare workers globally face an elevated risk of mental health conditions. Despite the critical need for mental health support, access remains inconsistent, hindered by both systemic gaps and barriers like stigma and regulatory constraints. Recognizing this unmet need, we established the Staff Mental Health Service (SMHS) in Cambridgeshire, UK, in September 2020. SMHS offers prompt assessments and treatments for healthcare workers across various professional roles.
Objectives: To assess costs, clinical outcomes and waiting times associated with treatment at the SMHS compared to NHS Talking Therapies (TT), a nationally-delivered primary care mental health service.
Methods: A cost-consequence analysis comparing costs and clinical outcomes for a hypothetical cohort of patients (N=1,000) between two options: (1) treatment either at SMHS or TT ; and (2) treatment at TT only. SMHS costs and outcomes were collected from routinely collected patient-level data, while those for TT were informed by published literature. Only costs borne by the health system were assessed; and model outcomes were compared for one treatment period (i.e., from treatment start to discharge). Primary model outcomes included average total treatment costs (GBP - £); and mean score changes on the Patient Health Questionnaire (PHQ-9) and Generalized Anxiety Disorder Assessment (GAD-7) measures for symptoms of depression and anxiety, respectively. Uncertainty in model parameters was explored using deterministic and probabilistic sensitivity analyses. Mean waiting times from referral to initial assessment and first treatment appointment for the SMHS and TT were analysed independently.
Results: Average total treatment costs per patient for the option consisting of treatment at either SMHS or TT was £825 less costly than the option consisting of treatment only at TT (£617 vs £1,442). Main drivers of cost difference included the notably higher cost and average number of appointments associated with treatment at TT. Treatment at either SMHS or TT also led to better patient outcomes on both the PHQ-9 (mean score reductions of 7.2 vs 6.1) and GAD-7 (mean score reductions of 6.3 vs 4.8) scales. Mean waiting times (days) for treatment at SMHS were considerably shorter than at TT: referral to initial assessment (19 vs 25 days); and referral to first treatment appointment (28 vs 53 days).
Conclusions: Preliminary results showed that a specialised mental health service for healthcare workers was associated with lower costs, better patient outcomes, and shorter waiting times compared to standard treatment options.

The FareAssieme Model of Trento: Empowering Community Psychiatry through Peer Support Experts

W. A. R. Di Napoli[1*], D. Scordato[1], O. Andreatta[2], S. Biasi[2], R. Pederzolli[2] and C. Agostini[1]

[1]Trento Mental Health Center, Azienda Provinciale per i Servizi Sanitari - Trento and [2]Il Cerchio Fareassieme, Trento, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.322

Introduction: "FareAssieme" ("Doing Together") is a community psychiatry approach adopted by the Mental Health Service of Trento (SSM) since 1999. It is based on the active involvement of users and families, valuing "experiential knowledge"—the insights gained from their experiences with illness and recovery—to enhance mental health care and rehabilitation pathways.
Objectives: To describe the "FareAssieme" model and analyze the effectiveness of Peer Support Experts (ESPs) in recovery processes, stigma reduction, and improving patient-perceived quality. ESPs are users or family members who have achieved life balance in their recovery journey and developed coping skills, sharing their stories to support others within the SSM of Trento.
Methods: The approach was implemented by systematically including ESPs in all SSM areas, such as front-office services, community mental health teams, territorial and hospital crisis areas, and residential facilities. Evaluation methods included satisfaction questionnaires, systematic PREMs and PROMs (Patient-Reported Experience and Outcome Measures), focus groups, and direct field observations, with particular attention to integrating ESPs into professional teams.
Results: Introducing ESPs led to significant service quality improvements, increased active user involvement, and a better working climate. Patients reported greater trust in services and enhanced recovery experiences. ESPs helped overcome users' initial resistance, especially among those less willing to trust health

services, fostering stronger therapeutic relationships. Professional resistance diminished as the added value of ESPs became evident. The "FareAssieme" model also fostered the establishment of a Participatory Planning Group (GPP), a diverse team including ESPs and professionals. The GPP discusses relevant topics for the SSM's operations and has produced several "Operational Guidelines"—recommendations compiled into booklets serving as operational instructions for all users, families, and service operators.
Conclusions: The "FareAssieme" model in Trento represents an effective example of recovery-oriented community psychiatry. ESPs have uniquely contributed to improving perceived service quality and promoting a culture of respect and co-participation, reducing the stigma associated with mental illness. The GPP has also served as a representative for mental health issues, voicing the SSM's shared views through mass media to disseminate anti-stigma messages.

Level of functioning and symptoms in children and adolescents with early-onset psychosis - baseline characteristics of participants in the OPUS YOUNG trial

N. K. Andersen[1,2]*, N. Larsen[1,2], C. F. Nielsen[1,2], T. L. Andersen[1,2], M. S. Madsen[1,2], A. K. Pagsberg[1,2] and T. O. Y. group[1,2]

[1]Child and Adolescent Mental Health Center, Copenhagen University Hospital –Mental Health Services CPH and [2]Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.323

Introduction: Level of functioning is often severely affected in individuals diagnosed with psychosis. Often, negative symptoms have been proposed as an important treatment target to improve functioning. Most research on the topic is conducted in adult samples, but the functional impairments associated in adolescents with schizophrenia spectrum disorders might differentiate from adults. A detailed understanding of the functional impairments and its association to clinical symptoms is important to develop meaningful and effective treatments adjusted to the needs of this young patient group.
Objectives: The aim of this study is 1) to explore functional capacity across different domains of function, and 2) to examine associations between functioning and clinical symptoms in youth with early-onset psychosis.
Methods: The study sample consists of 290 children and adolescent aged 12-17 years with early-onset psychosis included in the OPUS YOUNG trial. All participants' level of functioning was assessed with the Personal and Social Performance Scale (PSP), ranged 0-100. The level of psychosis symptoms was assessed with Scale for the Assessment of Positive Symptoms in Schizophrenia (SAPS) and Scale for the Assessment of Negative Symptoms in Schizophrenia (SANS). Data on affective symptoms, duration of untreated psychosis, cognitive functioning, quality of life, and substance use was also collected.
Results: The participants had a mean age of 15.6 (SD=1.6) years and 72% were females. Mean PSP total score was 49.9 (SD=13.8) and most participants had manifest to marked difficulties on the domains Socially useful activities, Personal and social relationships, and Self-care. Few participants had impairments in the domain of Disturbing and aggressive behavior. On average, levels of positive symptoms, negative symptoms, disorganized symptoms, and affective symptoms were of mild severity. Preliminary correlation analyses showed that all symptom categories were statistically significantly associated with PSP total score, and negative symptoms showed the strongest association.
Conclusions: Level of functioning was markedly impaired across most domains while symptom levels were of mild severity in most participants. We suggest that improvement of functioning should be a primary treatment target in parallel with symptom alleviation of this patient group.

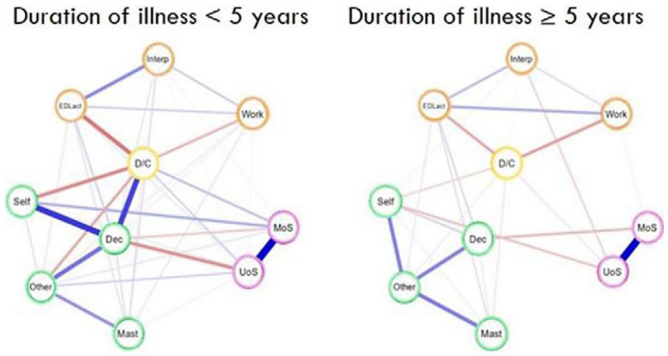
Metacognitive Functioning and its Relationship with Clinical Insight and Functional Outcomes in Schizophrenia: The Role of Illness Duration



C. Brasso[1]*, A. Carluccio[1], G. Colli[1], C. Montemagni[1], R. Sgro[1] and P. Rocca[1]

[1]Neuroscience, University of Turin, Turin, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.324

Introduction: Understanding the complex interplay between cognitive and functional domains in schizophrenia is crucial for improving patient functional outcomes.
Metacognition has emerged as a critical factor in the functioning and rehabilitation of individuals with schizophrenia. Additionally, the role of disorganization and clinical insight in this complex disorder has been extensively studied due to their role in shaping in the trajectory and real-life functioning outcomes of the disorder.
Objectives: This study aimed to assess the differences and relationships between disorganization, clinical insight, metacognition, and various functional domains in patients with short (< 5 years) and long (≥ 5 years) illness duration.
Methods: A network representation of the relationships between variables and the calculation of centrality and clustering indices were performed within each group. The two groups were compared with a network comparison test.
Results: Eighty-nine patients with early and one hundred and six with late phase SZ were included. We found no significant differences in the overall network structure between the two groups despite patients with longer illness duration showing significant worsening across all examined domains. Interestingly, the relationships between the network variables remained stable regardless of disease duration.
One notable difference emerged in the correlation between interpersonal functioning and unawareness of symptoms, negatively correlated only in the group with longer illness duration. These results suggest that the link between social functioning and clinical insight may become more pronounced as the disorder progresses.

Decentration was more central in the group with short disease duration, whose patients do not yet show marked impairment of metacognition, particularly in the 'understanding other's mind' domain. Regarding clustering indices in the group with short illness duration, the misattribution of symptoms to the disorder is more clustering. On the other hand, metacognitive mastery, was highly clustering in both the short and long illness duration.

Image 1:

Node	Meaning
Interp	SLOF- Interpersonal relationships
EDLact	SLOF- Everyday activities
Work	SLOF- Work skills
Self	MAS- Self-reflectivity
Dec	MAS- Decentration

Node	Meaning
Other	MAS- Awareness of other
Mast	MAS- Mastery
MoS	SUMDa Misattribution of symptoms
UoS	SUMDc Unawareness of symptoms
D/C	PANSS- Disorganization

Conclusions: The stability of the relationships between metacognitive variables, clinical insight, and functional outcomes, regardless of disease duration, suggests that interventions targeting metacognition may be beneficial for improving functioning in patients with schizophrenia. Additionally, the emerging negative correlation between interpersonal functioning and unawareness of symptoms in patients with longer illness duration highlights the importance of addressing both social skills and clinical insight as the disease progresses. These findings underscore the potential utility of integrated treatment approaches that address cognitive, social, and functional domains to optimize functional outcomes for individuals with schizophrenia across the course of the illness.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.325

Introduction: Psychotic experiences (PEs) are subclinical symptoms of psychosis affecting about 10% of children and adolescents. They may cause significant distress and impair daily functioning. Moreover, when persisting over time they are more likely to result in psychotic disorders.
Objectives: This longitudinal study aimed at assessing the effects of polygenic and environmental risk factors for schizophrenia on distressing and persisting PEs in a cohort of adolescents.
Methods: Data were obtained from participants of European ancestry derived from the *Adolescent Brain and Cognitive Development Study,* Release 5.1. Past-month PEs were assessed using the *Prodromal Questionnaire-Brief Child Version.* The primary outcome was distressing PEs at 3-year follow-up. Secondary outcomes included varying levels of persistence of distressing PEs, occurring in 1, 2, 3, or all 4 waves. Polygenic risk score for schizophrenia (PRS-SCZ) was calculated using the continuous shrinkage approach (PRS-cs). The exposome score for schizophrenia (ES-SCZ) was generated by summing up the weighted risk of nine environmental exposures across lifetime: emotional neglect, physical neglect, emotional abuse, physical abuse, sexual abuse, cannabis use, winter birth, hearing impairment, and bullying. Multilevel logistic regression was carried out to test the individual associations of PRS-SCZ and ES-SCZ with the outcomes; the relative excess risk due to interaction was calculated to determine the additive interaction between PRS-SCZ and ES-SCZ on distressing PEs. Main analysis was adjusted for age and sex as covariates; sensitivity analysis also included family income and parental education.
Results: ES-SCZ was significantly associated with 3-year follow-up distressing PEs (OR 1.27 [95% CI 1.14, 1.43], p<.001) and lifetime distressing PEs at all degrees of persistence, with an increasing magnitude of association for a higher degree of symptom persistence (≥1 wave: OR 2.77 [95% CI 2.31, 3.31], p<.001; ≥2 waves: OR 3.16 [95% CI 2.54, 3.93], p<.001; ≥3 waves: OR 3.93 [95% CI 2.86, 5.40], p<.001; all 4 waves: OR 3.65 [95% CI 2.34, 5.70], p<.001). PRS-SCZ was significantly associated with distressing PEs persisting for more than one (OR 1.29 [95% CI 1.08, 1.53], p=.040) or two waves (OR 1.34 [95% CI 1.08, 1.65], p=.070) and also additively interacted with ES-SCZ for these outcomes (≥1 wave: RERI 1.26 [95% CI 0.14, 2.38], p=.027; ≥2 waves: RERI 1.79 [95% CI 0.35, 3,23] p=.015). Sensitivity analysis confirmed all main results.
Conclusions: PRS-SCZ and ES-SCZ showed independent and joint effects on distressing PEs. The more pronounced contribution of ES-SCZ on distressing PEs and its gradient effects on the degree of persistence calls for particular attention to environmental risk

factors for schizophrenia on the development and persistence of PEs.

Illness uncertainty, psychological well-being and psychological resilience in people with schizophrenia

G. Sahin-Bayindir[1], S. Gunay[2], S. Er[1]* and B. K. Gultekin[3]

[1]Florence Nightingale Faculty of Nursing, Department of Mental Health and Psychiatric Nursing, Istanbul University - Cerrahpasa; [2]Psychiatric Clinic and [3]Pul Clinic, Erenkoy Mental Health and Neurology Training and Research Hospital, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.326

Introduction: Patients with schizophrenia experience uncertainty due to unpredictable symptoms, disease progression and lack of information about the illness, treatment and prognosis. Studies underline that illness uncertainty is a risk factor in schizophrenia, while psychological well-being and quality of life are critical outcomes. Psychological resilience is also recognised as having a mediating role.
Objectives: The aim of this study was to examine the relationships between illness uncertainty, psychological resilience and psychological well-being in people with schizophrenia.
Methods: In this cross-sectional study, 150 participants with a diagnosis of schizophrenia (DSM-5) were recruited. Data were collected using the Mishel Uncertainty in Illness Scale-Community Form, the Psychological Well-being Scale and the Connor-Davidson Resilience Scale. Data were analysed using descriptive statistics, independent samples t-test, one-way ANOVA and pearson correlation analysis.
Results: The mean age of people diagnosed with schizophrenia who participated in the study was 37.52±10.62 years, 41.3% (n=62) were high school graduates, 68.7% (n=103) were single, 53.3% (n=80) had income equal to expenses, 59.3% (n=89) were not working, 54.7% (n=82) lived with their parents and 38.7% (n=58) had children. The study found a negative and weak relationship between the mean MUIS-C total score and the mean PWBS total score (r=-0.359), and also a negative and weak relationship between the mean MUIS-C total score and the mean CD-RISC total score (r=-0.287).
Conclusions: It is important for health professionals to assess the uncertainty experienced by people with schizophrenia, to examine its impact on their psychological well-being and to understand how they cope with their illness.

doi: 10.1192/j.eurpsy.2025.327

Introduction: The increasing prevalence of metabolic syndrome in persons with schizophrenia has driven research into the underlying mechanisms of its pathophysiology. Overlapping neurobiological profiles of metabolic risk factors and psychiatric symptoms, particularly shared genetic liabilities, suggest that oxytocin system dysfunction may be a common mechanism underlying both schizophrenia and metabolic syndrome. Given its prosocial and anorexigenic effects, intranasal oxytocin has been studied for its therapeutic potential in schizophrenia and obesity. However, the pathophysiology and mechanisms of oxytocin in schizophrenia are complex and it is too early to draw definitive conclusions.
Objectives: This study aims to investigate the correlation between plasma oxytocin levels and metabolic syndrome and to test whether oxytocin system dysfunction could serve as a putative endophenotypic marker of schizophrenia.
Methods: This prospective cohort study involved 90 persons with schizophrenia, all of whom were responsive and maintained on stable monotherapy with either olanzapine, risperidone, or aripiprazole, without any alterations to their antipsychotic regimen, alongside 60 healthy controls. All participants were followed for 24 months. Anthropometric measurements, metabolic parameters, and the presence of metabolic syndrome were assessed. Plasma oxytocin levels were measured. The psychopathology of persons with schizophrenia was evaluated using the Positive and Negative Syndrome Scale (PANSS), and quality of life was assessed using the World Health Organization Quality of Life (WHOQOL-BREF) scale. Other potential confounding factors, including dietary habits, caffeine and nicotine use, and menstrual cycle, were considered in the analysis.
Results: Plasma oxytocin levels were inversely associated with the presence of metabolic syndrome in persons with schizophrenia, regardless of antipsychotic treatment. Persons with schizophrenia who had metabolic syndrome at baseline showed lower baseline plasma oxytocin levels. Among those with metabolic syndrome at baseline, higher plasma oxytocin levels were associated with better metabolic parameters at the end of the follow-up period. Conversely, for those without metabolic syndrome at baseline, lower plasma oxytocin levels were predictive of a higher risk of developing metabolic syndrome over time.
Conclusions: This study highlights the potential role of oxytocin in the pathophysiology of metabolic syndrome in schizophrenia. Lower plasma oxytocin levels were associated with both the presence and risk of developing metabolic syndrome, suggesting that oxytocin system dysfunction may contribute to metabolic dysregulation in schizophrenia. These findings support the hypothesis that oxytocin could be a putative endophenotypic marker for metabolic vulnerability in schizophrenia, while future studies should further investigate the therapeutic implications of targeting the oxytocin system.

doi: 10.1192/j.eurpsy.2025.328

Introduction: Childhood trauma (CT) and bullying have been shown to be associated with autistic traits (AT) and to mediate the relationship between AT and psychotic experiences (PEs). Understanding how different childhood adversity subtypes influence distinct domains of PEs can provide important insights for preventing PEs in individuals with high AT.
Objectives: This study aimed to investigate the impacts of childhood adversity subtypes on the relationship between AT and PEs in a general population twin sample.
Methods: We analyzed data on 792 twins and siblings from the first wave of the TwinssCan Project, a longitudinal general population twin cohort. AT were measured using the Autism-Spectrum Quotient (AQ), and PEs using the Community Assessment of Psychic Experiences (CAPE) which consists of three subscales (positive, negative and depressive). CT subtypes were assessed using the Childhood Trauma Questionnaire (CTQ), evaluating emotional, physical, and sexual abuse, as well as emotional and physical neglect. Bullying was assessed using the Retrospective Bullying Questionnaire (RBQ). Multilevel linear regression analyses were conducted. Positive, negative, and depressive PEs were regarded as the dependent variables, interactions of CT subtypes and bullying with total AQ were regarded as independent variables in separate models. All models were adjusted for age and sex. Bonferroni correction ($p<0.008$) was applied for multiple comparisons.
Results: The mean of the age of the participants was 17.5 ± 3.6 years and 60.2% of the sample was female. Emotional abuse (B = 0.12, 95% CI: 0.08 to 0.15), physical abuse (B = 0.15, 95% CI: 0.07 to 0.22), sexual abuse (B = 0.10, 95% CI: 0.03 to 0.16), emotional neglect (B = 0.05, 95% CI: 0.02 to 0.09) and physical neglect (B = 0.07, 95% CI: 0.03 to 0.11) significantly moderated the positive relationship between AT and positive PEs. However, only emotional abuse uniquely moderated the relationship between AT and both negative and depressive PEs (B = 0.09, 95% CI: 0.04 to 0.13; B = 0.09, 95% CI: 0.04 to 0.14) with physical neglect showing a trend toward significance for depressive PEs (B = 0.08, 95% CI: 0.02 to 0.13). Bullying did not moderate any domain of PEs.
Conclusions: Emotional abuse may play a unique role in moderating the relationship between AT and PEs, affecting all domains of psychosis expression. Conversely, other forms of CT predominantly influence positive PEs. Further research is needed to clarify the distinct pathways through which distinct types of childhood adversity impact the association between AT and PEs.

Support Group for Relatives of Patients with First Psychotic Episode. When Crisis Mobilizes the System. Windows of Opportunity and Change

L. Moreno Fernández[1]*, A. R. Diez[1], B. R. Fernandez[1], J. S. Yepes[1], R. G. Rincon[1] and P. C. Moreno[1]

[1]Hospital Ramón y Cajal, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.329

Introduction: First psychotic episodes (FPE) have a significant impact not only on the individual who experiences them but also on their close environment, particularly their family. The onset of a FPE typically occurs in the early twenties, a stage of life where individuals are planning and developing their adult life project. The changes in family dynamics following a FPE are part of the recovery process and are considered a prognostic factor for recovery.
Since the beginning of the Comprehensive Care Program for First Psychotic Episodes, a weekly support group for families has been conducted. The group is open, lasts 90 minutes.The group has an open theme and is co-facilitated. Participants may attend after starting the psychoeducation workshop for FPE and can continue attending even after the patient has been discharged from the facility.
Objectives: The aim is to analyze the predominant family figures, age range, and gender, as well as the main themes that arise and concern the families of patients with first psychotic episodes.
Methods: A retrospective study with a mixed-method approach (qualitative and quantitative) is proposed, based on the narrative records collected during the weekly sessions from 2023 until June 2024.
Results: The average attendance is 10.7 participants per group, mostly women (80%). The range age is from 18 to 70 years, with

and average of 58 years. In terms of the roles concerning the patient: parents (95%), siblings (5%), with no representation of partners during the period analysed.
The predominant themes identified from the analysis of the collected *verbatims* include: guilt regarding the onset of the illness; the timing of recovery and managing the sense of urgency from the institution, the family, and the patient; regression in relational family dynamics; caregivers' fear of their own death; shame and stigma; the traumatic experience of hospitalization; the distinction between behaviors associated with personality versus the illness; the rupture with identity; the fear of relapse and suicide.
Families highlight the role of the group as an emotional support, an improvement in communication strategies and bonding with the sick relative, better capacity for mentalization, and managing their own anxieties and emotions related to guilt and self-care.
Conclusions: The onset of a FPE generally affects the entire family system. Past conflicts and regressive attachment dynamics are activated. Communication based on guilt harms the elements of the system. Family support groups play a crucial role in the recovery process and in helping to establish new dynamics that promote the well-being and autonomy of both the patient and caregivers. The group stands out as a source of hope, which is the main healing factor. Additionally, participants report gaining healthy coping tools and reducing their experience of isolation and stigma.

Service disengagement in first episode psychosis: rates and predictors form 2-year longitudinal research in a real-world care setting

L. Pelizza[1], E. Leuci[2], E. Quattrone[2], M. Menchetti[1] and F. Catalano[3]*

[1]Università di Bologna, Bologna; [2]AUSL di Parma, Parma and [3]University of Bologna Italy, Bologna, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.330

Introduction: Service disengagement is a major problem for "Early Intervention in Psychosis" (EIP). Understanding predictors of engagement is also crucial to increase effectiveness of mental health treatments, especially in young people with First Episode Psychosis (FEP). No Italian investigation on this topic has been reported in the literature to date. The goal of this research was to assess service disengagement rate and predictors in an Italian sample of FEP subjects treated within an EIP program across a 2-year follow-up period.
Objectives: The goal of this research was to assess service disengagement rate and predictors in an Italian sample of FEP subjects treated within an EIP program across a 2-year follow-up period.
Methods: All patients were young FEP help-seekers, aged 12–35 years, recruited within the "Parma Early Psychosis" (Pr-EP) program. At baseline, they completed the Positive And Negative Syndrome Scale (PANSS) and the Global Assessment of Functioning (GAF) scale. Univariate and multivariate Cox regression analyses were carried out.
Results: 489 FEP subjects were enrolled in this study. Across the follow-up, a 26 % prevalence rate of service disengagement was found. Particularly strong predictors of disengagement were living with parents, poor treatment adherence at entry and a low baseline PANSS "Disorganization" factor score.
Conclusions: More than a quarter of our FEP individuals disengaged the Pr-EP program during the first 2 years of intervention. A possible solution to reduce disengagement and to facilitate re-engagement of these young patients might be to offer the option of low-intensity monitoring and support, also via remote technology and telemental health care.

In the waiting line: a narrative analysis of patients and caregivers waiting for early intervention psychosis services in Canada

F. Poukhovski-Sheremetyev[1,2]*, Y. Pelling[3], J. Denny[4], A. Abdel-Baki[5], S. Iyer[1,2] and V. Noel[2]

[1]Department of Psychiatry, McGill University; [2]Douglas Hospital Research Centre, Montreal; [3]SPOR National Training Entity, Quebec City; [4]Cape Breton University, Cape Breton and [5]Department of Psychiatry and Addictions, University of Montréal, Montreal, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.331

Introduction: Our patients often come to us through wait-lists, but when does the wait really start? Early intervention psychosis programs have introduced policies and benchmarks aimed at minimizing the time between referral and first contact. While programs that meet these targets are often celebrated for their success in reducing untreated psychosis, these targets leave out a critical piece of the puzzle: the time elapsed from symptom onset. Understanding how patients and caregivers experience the wait for care in its entirety is critical to further reducing treatment delays in psychosis.
Objectives: This presentation aims to first examine a disconnect between early intervention wait-list policies and patients' experiences. Next, it will explore how patient and family member narratives reflect the complex and nuanced nature of waiting for care. Finally, it will propose clinically relevant solutions for reducing the delay between symptom onset and appropriate treatment.
Methods: We conducted individual semi-structured interviews with patients and caregivers accessing early intervention psychosis services across Canada. For this presentation, three interviews from different geographic and socio-cultural regions were selected for their distinct perspectives. We performed a two-reviewer narrative inquiry to derive emergent narratives about waiting for services.
Results: Patient and caregiver experiences revealed two distinct waiting periods. Aside from the "wait-list" period between referral and first contact that is addressed by early intervention policies, participants noted experiencing a much longer initial waiting period, with narratives beginning at symptom onset. Participants described this period as an active, dynamic, frustrating, and often

traumatic process that involves multiple ER visits and attempts at receiving care.
Conclusions: We propose formally distinguishing between two forms of waiting for services: passive waiting, which is the state of being on a wait-list, and active waiting, which begins at symptom onset and includes the complex struggle to receive stable care. Early intervention programs' efforts to reduce passive waiting are important, but the high burden of active waiting suggests a need for larger efforts such as clinician education and systemic changes in how patients access healthcare. Reducing active wait times could truly transform how first episode psychosis is managed and improve outcomes for those in urgent need.

Perfectionistic concern profile as a risk factor for suicide-related behaviour in adolescents: Results from the EPISAM-School Study

A. De La Torre-Luque[1,2*], P. Diaz-Carracedo[1], A. Garcia-Ramos[1], W. Ayad-Ahmed[1,3], A. Sanchez[4], S. Doval[1], C. Perez-Guerra[5], A. Pemau[1] and L. J. Gonzalez-Agudelo[1]

[1]Complutense University; [2]CIBERSAM ISCIII; [3]Hospital Clinico San Carlos, Madrid; [4]Barcelona University, Barcelona and [5]Autonomous University of Madrid, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.332

Introduction: Adolescents are at increased risk of developing suicide-related behaviour (SRB). Varying contributing factors may play an important role across the different forms of SRB. Perfectionistic concerns may become a cognitive moderator influencing volitional moderators (e.g., non-suicidal self-harm, NSSH) and suicidal ideation escalation.
Objectives: To identify profiles of perfectionistic concerns in a community sample of adolescents. Also, to study the relationship between suicide-related outcomes and NSSH, according to perfectionism profile.
Methods: A sample of 1,526 adolescents (54.3% female; *M*= 13.81 years, *SD*= 1.28) participated in our study. A wide range of SRB and motivational and volitional risk factors were evaluated in school settings. Six types of perfectionistic concerns, assessed by the Frost Multidimensional Perfectionism Scale (FMPS), were used to identify perfectionism profiles, through latent profile analysis.
Results: Almost one in five adolescents (19.5%) showed SRB risk and more than one in three adolescents (35.1%) engaged in NSSH in the last year. Five profiles of perfectionism were identified (Figure 1). The profile featured by higher concerns across perfectionistic domains (7.2% of participants) showed significant relationship with SRB risk (OR = 2.84) and suicidal ideation (OR = 1.22), in comparison to the minimal concern profile. On the other hand, the profile featured by high parental concerns (18.2% of adolescents) was associated with increased risk of ideation (OR = 2.75) and NSSH (OR = 1.51).

Image 1:

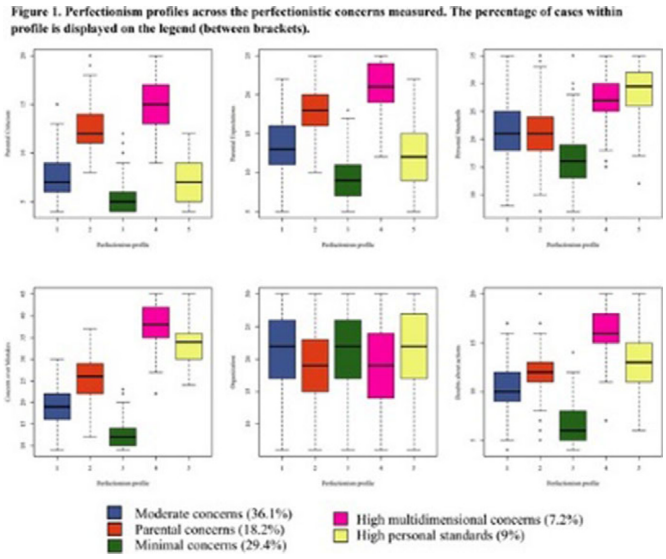

Figure 1. Perfectionism profiles across the perfectionistic concerns measured. The percentage of cases within profile is displayed on the legend (between brackets).

Conclusions: Perfectionism may constitute a key risk factor for NSSH and SRB development. The promotion of prevention programmes to enhance cognitive regulation skills may help prevent suicide in adolescents.

Epidemiology of suicidal behavior in Catalonia, Spain

A. Giménez-Palomo[1*], D. Hidalgo-Mazzei[1], E. Vieta[1] and A. Benabarre[1]

[1]Hospital Clínic of Barcelona, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.333

Introduction: Suicide is a global public health issue. According to the World Health Organization (WHO), more than 700,000 people die by suicide worldwide each year. In 2019, it was the fourth leading cause of death among those aged 15 to 29 globally. In Spain, suicide has been the leading cause of external death in recent years, which has motivated in some regions the implementation of preventive strategies, such as *Codi Risc de Suïcidi* (Suicide Risk Code).
Objectives: This study examines the epidemiology of suicidal behavior in the Catalan population between 2010 and 2019, exploring geographical disparities and the influence of different sociodemographic and clinical variables on the incidence of suicidal ideation and suicide attempt.
Methods: All residents in Catalonia who attended the public health system from 2010 to 2019 were included in the study. Data were obtained from the *Program d'analítica de dades per a la recerca i la innovació en salut* (PADRIS) of the *Agència de Qualitat i Avaluació Sanitàries de Catalunya* (AQuAS). Data on geographical,

sociodemographic, and clinical variables were collected for subsequent statistical analysis. Statistical significance was set at $p<0.05$.
Results: A total of 1,421,510 individuals were included. Overall, 6921 cases of suicidal ideation (0.5%) and 1143 suicide attempts (0.1%) were registered, which an accumulated incidence of 487/100,000 inhabitants for the first outcome and 804/1,000,000 inhabitants for the second. From the whole sample, 83,592 individuals (5.9%) had a severe mental illness (SMI), whereas the proportion of patients with a SMI in the group of suicide attempters was 9.6%. The majority of individuals who attempted suicide were women (64.1%). The highest proportion of individuals with suicidal thoughts or attempts was found in the age range from 15 to 19 years. The presence of a somatic illness, low socioeconomic status, tobacco use and the presence of a severe mental illness were significantly associated with suicidal ideation and attempt. Those patients with suicidal behavior had a higher number of emergency visits during the 10-year period, and also a higher probability of being prescribed antidepressants, antipsychotics, benzodiazepines or lithium. Geographical disparities in the incidence of suicidal behavior were found, with specific regions showing higher rates. In a logistic regression analysis, all associations remained significant.
Conclusions: This study highlights the association between sociodemographic and clinical factors, which should have been assessed in clinical practice, with suicidal behavior. Geographical disparities may be attributed to various factors, including access to mental health services and socioeconomic factors. This study underscores the importance of identifying specific profiles at a higher risk for committing suicide, and also to implement policies and prevention programs in order to address this public health issue comprehensively.

Risk of Suicide Related to Mental Disorders in Catalonia, Spain: A Population Registry-Based Cohort Study

P. Mortier[1,2*], L. Latorre-Moreno[1], F. Amigo[1,2,3], M. López[1], A. Portillo-Van Diest[1,2,4], L. Ballester[1,2], J. Alonso[1,2,4] and G. Vilagut[1,2]

[1]Health Services Research Group, Hospital del Mar Research Institute, Barcelona; [2]Centro de Investigación Biomédica en Red de Epidemiología y Salud Pública, Instituto de Salud Carlos III (CIBERESP, ISCIII), Madrid, Spain; [3]Department of Population Health Sciences, Duke University School of Medicine, Durham, United States and [4]Department of Experimental and Health Sciences, Pompeu Fabra University, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.334

Introduction: Registry-based studies are efficient to investigate population mental health and suicide risk, but are largely absent in Europe outside of Scandinavia and the UK.
Objectives: To investigate suicide risk associated with mental disorders in the Catalan population (7.6 million), stratified by gender and history of psychiatric hospitalization.
Methods: Population-representative retrospective registry-based cohort study including 764,938 Catalan residents in the period 2014-2019. Data sources included suicide mortality, electronic health registries from five healthcare settings, and administrative data. Suicide deaths were identified through judicial death registers using ICD-10 codes X60-X84. ICD-9CM and ICD10CM codes from all inpatient and outpatient healthcare contacts were used to categorize 109 mental disorders. Age-sex standardized mortality ratios (SMRs) were calculated using indirect standardization, with expected deaths based on official general population mortality rates in Catalonia.
Results: Suicide risk was significantly elevated among Catalan residents diagnosed with any mental disorder (SMR [95%CI] = 1.6 [1.3-1.9] for females; SMR = 1.8 [1.6-2.0] for males). In females, suicide risk was highest for sedative or hypnotic abuse (SMR = 46.1 [3.7-88.5]), cocaine abuse (SMR = 42.8 [9.0-76.6]), borderline personality disorder (SMR = 33.0 [10.7-55.3]), polysubstance abuse (SMR = 32.9 [2.1-63.8]), and mental disorder not otherwise specified (SMR = 24.9 [11.7-38.1]). In males, risk was highest for obsessive-compulsive disorder (SMR = 20.2 [10.7-29.8]), acute and transient psychotic disorders (SMR = 17.9 [1.1-34.8]), mental disorder not otherwise specified (SMR = 17.2 [10.1-24.3]), paranoid schizophrenia (SMR = 16.8 [9.4-24.1]), and opioid abuse (SMR = 16.1 [1.6-30.6]). Suicide risk was substantially elevated in individuals with a history of psychiatric hospitalization (SMR = 18.3 [15.5-21.2]] for females; SMR = 13.4 [12.0-14.8] for males). In females with psychiatric hospitalization history, risk was highest for dependence on stimulants other than cocaine (SMR = 105.4 [11.6-199.3]), attention deficit hyperactivity disorder (SMR = 86.2 [19.2-153.2]), polysubstance abuse (SMR = 66.0 [33.6-98.3]), opioid abuse (SMR = 60.1 [2.1-118.1]), and cocaine abuse (SMR = 57.2 [32.6-81.8]). In males with psychiatric hospitalization history, risk was highest for obsessive-compulsive disorder (SMR = 45.7 [30.6-60.8]), schizoid personality disorder (SMR = 36.9 [13.5-60.2]), unspecified disorders of adult personality and behaviour (SMR = 35.0 [9.6-60.3]), schizotypal disorder (SMR = 34.3 [6.7-61.9]), and histrionic personality disorder (SMR = 32.5 [1.2-63.9]).
Conclusions: Risk of suicide in the Catalan population varies substantially by mental disorder type, gender, and psychiatric hospitalization history, highlighting the need for targeted and diversified prevention strategies.

Machine learning model development to retrospectively predict suicide attempts in the Millenium Cohort Study sample

C. Peña Gómez[1,2*], M. Fradera[1,2,3], M. Caravaca[1,2], D. Roche[4], J. Giraldo[1,2,3] and D. Palao[1,2,3]

[1]Unitat de Neurociència Traslacional, Institut d'Investigació i Innovació Parc Taulí (I3PT-CERCA), Sabadell; [2]Institut de Neurociències (INc), Universitat Autònoma de Barcelona, Bellaterra; [3]Centro de Investigación Biomédica en Red de Salud Mental, Instituto de Salud Carlos III, Madrid and [4]Research Institute for Evaluation and Public Policies (IRAPP), Universitat Internacional de Catalunya (UIC), Barcelona, Spain

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.335

Introduction: Suicidal behavior is a complex phenomenon that affects all demographics, with children and adolescents being particularly vulnerable. It is associated with multifactorial conditions that must be considered for the development of more effective prevention strategies. The use of machine learning (ML) models to predict suicide attempts is becoming widespread, as they allow for the simultaneous testing of numerous factors, their complex interactions, and non-linearity in predictive model creation. The Millennium Cohort Study (MCS) is an observational, multidisciplinary cohort study that encompasses a wide range of dimensions, including psychological, genetic, biological, familial, social, and economic factors, as well as traumatic life events, family history, and medical history. This allows for the exploration of their relationship with suicidal behavior throughout individual development using ML models.

Objectives: The aim was to develop a statistical method that applies ML models to retrospectively predict suicide attempts using structured tabular data from an adolescent cohort defined by the MCS.

Methods: The sample consists of 9,824 MCS participants (age 17) who were asked if they had ever purposely hurt themselves in an attempt to end their life. Of these, only 7.4% (725) responded affirmatively. Before starting the modeling phase and fine-tuning any algorithm, several stages were completed: data cleaning, feature extraction and engineering, and feature scaling and selection. We used a wide range of algorithms, from low-complexity (linear regression) to high-complexity (neural networks), while tracking their effectiveness, robustness, generalization, sensitivity, and accuracy.

Results: Even though overall accuracy ranged from 0.83 to 0.87, we generally obtained low f1-scores (˜0.45-0.55) for the targeted class (suicide attempt) and high f1-scores (˜0.95) for the control class. Similar results were observed for precision scores; however, the recall scores were good for both classes, ranging from 0.67 to 0.87. The best performing models were logistic regression and neural networks.

Conclusions: These preliminary results shows that ML models trained with multidimensional data from a young cohort are sensitive in classifying individuals who have attempted suicide. We aim to improve the f1-score and area under the curve (AUC) metrics for the target class through several techniques: over/under-sampling, target encoding, class weight adjustments, ensemble methods, and various neural network architectures.

Early Interventions for Preventing Self-Harm Recurrence: A Systematic Review and Meta-Analysis

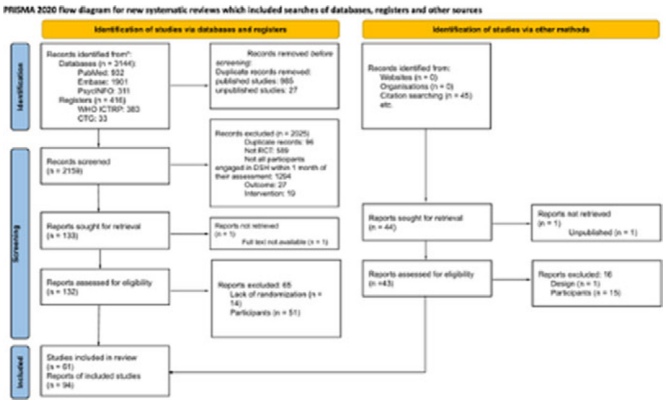
G. P. Roncete[1*], L. C. Farhat[2], L. Beiram[2], K. L. Ramirez[3], M. H. Bloch[3], R. F. Damiano[2] and E. C. Miguel[2]

[1]Faculdade de Medicina da Universidade de São Paulo; [2]Departamento e Instituto de Psiquiatria, Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil and [3]Yale Child Study Center, Yale University School of Medicine, New Haven, United States

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.336

Introduction: Deliberate self-harm (DSH) is a strong predictor of future suicide attempts (SAs), highlighting the need to evaluate interventions that reduce recurrence risk.



Objectives: This systematic review and meta-analysis aimed to evaluate pharmacological and non-pharmacological interventions for preventing repeated DSH in individuals recently engaged in DSH. We also examined how participants' characteristics and trial inclusion criteria impacted interventions' effectiveness.

Methods: Randomized controlled trials (RCTs) with participants engaged in DSH within one month before enrollment were included. Studies with participants showing only suicidal ideation or older DSH were excluded. We searched five databases (PubMed, Embase, PsycINFO, WHO ICTRP, and ClinicalTrials.gov) with no language restrictions through September 2023. Two reviewers independently selected studies and resolved discrepancies through discussion. Outcomes were assessed at three time points: T1 (0–6 months), T2 (6–12 months), and T3 (>12 months). The primary outcome was repeat DSH; secondary outcomes included suicidal ideation, suicide deaths, all-cause mortality, anxiety, depression, hopelessness, and quality of life. Interventions were categorized by type and delivery format (individual or group, remote or in-person).

Results: The PRISMA flowchart is shown in Image 1. Sixty-one trials involving 125 comparisons and 21,147 participants were included in this review. Average age was 31.5 years, with most being female (66.58%), unmarried (60.82%), and white (65.49%). Participants' history of self-harm was noted in 48 studies, with at least 56% having engaged in another act before inclusion. In 42 studies, suicidal intent was either not investigated or not required. The most common types of interventions were Treatment As Usual (TAU) (46 arms), Psychotherapy (36), and Active Contact and Follow-up (25). Interventions were primarily applied individually and in person (84), with Cognitive Behavioral Therapy (16) being the most frequent psychotherapy framework. Psychotherapies were associated with a reduced risk of new self-harm acts within the first six months (T1) compared to TAU (k = 12; N = 2110; OR = 0.69; 95% CI 0.48–0.99). Active contact and follow-up interventions

outperformed TAU in the longer-term follow-up (T3) (k = 4; N = 3724; OR = 0.83; 95% CI 0.70–0.99).

Image 1:

Conclusions: The superiority of psychotherapies at six months was not sustained at twelve months. However, active contact and follow-up interventions may offer benefits in reducing the risk of self-harm recurrence after one year.

Modeling data-driven clusters of social determinants of health (SDoH) and their associations with US suicide from 2009-2019

Y. Xiao[1]*, Y. Meng[1], T. T. Brown[2], A. C. Tsai[3], L. Snowden[2], J. C.-C. Chow[2], J. Pathak[1] and J. J. Mann[4]

[1]Weill Cornell Medicine, Cornell University, New York; [2]UC Berkeley, Berkeley; [3]Harvard Medical School, Boston and [4]Columbia University Irving Medical Center, Columbia University, New York, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.337

Introduction: Social determinants of health (SDOH) have been linked to disparities in suicide rates across various demographics, including racial/ethnic groups, sex, age, and geography in the U.S. However, most studies have focused on individual or selected SDOH, rather than examining comprehensive, multi-dimensional SDOH factors. A more nuanced understanding of how clusters of SDOH contribute to suicide disparities across counties is needed to inform targeted prevention strategies.
Objectives: To identify multi-dimensional SDOH county clusters and estimate their geographic and temporal associations with county-level suicide rates.
Methods: This study used national SDOH data from 3,109 U.S. counties over three time periods (2009, 2014, and 2019), matching them with county-level suicide rates from the National Vital Statistics System aggregated into three-year periods (2008-2010, 2013-2015, and 2018-2020). A total of 284 county-level SDOH variables, spanning six domains (social context, economic context, education, physical infrastructure, healthcare context, and natural environment), were analyzed using unsupervised machine learning algorithms to identify SDOH clusters. Associations between SDOH clusters and county-level suicide rates were estimated using negative binomial and LASSO regression.
Results: Three distinct SDOH clusters were identified (Figure 1):

- Cluster 1 ("REMOTE") included rural counties with elderly, marginalized populations and substandard housing.
- Cluster 2 ("COPE") represented counties with complex family dynamics, overburdened health systems, poverty, and extreme heat challenges.
- Cluster 3 ("DIVERSE") encompassed densely populated areas with immigrants, racial/ethnic minorities, environmental challenges, and economic inequality.

Geographically, REMOTE was more common in North and Central U.S., COPE in the South and Central U.S., and DIVERSE along the coasts. Suicide rates were highest in REMOTE counties, especially among men. COPE counties had elevated suicide rates among Whites, while DIVERSE counties saw higher rates among women and Black/Hispanic populations. Most counties (70%) remained within the same cluster over time, with stable suicide rate associations.
Conclusions: This study identified three multi-dimensional SDOH clusters that were associated with varying suicide rates across U.S. counties. These clusters offer insight into the social and environmental conditions contributing to suicide risk. Future prevention strategies should focus on addressing the distinct challenges within each cluster, such as housing inadequacies, healthcare access, and economic inequality, to reduce overall suicide rates and related disparities.

Machine learning based prediction of suicidal behaviors in patients with perinatal depression: a nationwide register-based cohort study

H. Yu[1]*, E. Hysaj[1], E. Bränn[1] and D. Lu[1]

[1]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.338

Introduction: Previous results show that women who suffered from perinatal depression (PND) have a higher risk of suicidal behavior. However, clinical tools for predicting suicidal behavior among patients with PND are lacking.
Objectives: To develop a prediction model for suicidal behavior after PND using machine learning.
Methods: Leveraging nationwide Swedish register data, we included 57,848 women with PND diagnosed during 2001-2018 and identified 2,303 events of suicidal behavior up to 5 years after PND diagnosis. Based on our previous association studies, 16 predictors containing information on demographics and pregnancy characteristics were included after multiple imputation. The sample was randomly split into 80% as a training set and 20% for testing. Classification and Regression Tree (CART), Random

Forest (RF), Naïve Bayes (NB) and Logistic regression (LR) were used to establish prediction models with area under the curve (AUC) assessed for prediction performance. 10-fold cross-validation was used to evaluate the algorithms on unseen data.
Results: In the prediction models, the CART yielded the best performance for suicidal behavior within 5 years after PND diagnosis (AUC 0.78, 95% CI 0.76-0.81). The population that scored highest (17%) in CART model had 84% risk of suicidal behavior. LR also had a comparable performance (AUC 0.78, 95% CI 0.76-0.81), whereas RF (AUC 0.74, 95% CI 0.72-0.76) and NB (AUC 0.70, 95% CI 0.68-0.72) had relatively poor performance. Notably, suicide history was a main contributor in all four models. Other predictors like household income, gestational age and education level were also important indicators of suicidal behavior risk.
Conclusions: The machine learning models have promising prediction performance for suicidal behavior after PND. Yet, further improvement is needed before clinical implementation.

Suicidality Calls to National Helpline After a Terror Attack and War

S. Blum[1] and G. Zalsman[1]*

[1]Geha Mental Health Center, Petah Tikva, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.339

Introduction: IMPORTANCE Changes in suicide rates after a nationwide trauma may be different from changes in psychiatric symptoms or general distress after such events. However, very few studies have examined short-term suicide-related reactions after such an event.
Objectives: To evaluate the short-term outcome of the events in Israel on October 7, 2023, a large-scale terror attack and unfolding war, on changes in suicidality as reflected in percentages of suicide-related calls in relation to all calls to a national mental health first aid helpline, the Israeli Association for Emotional First Aid (ERAN).
Methods: DESIGN, SETTING, AND PARTICIPANTS The data included all interactions via the various ERAN helpline services between January 1, 2022, and December 31, 2023.
EXPOSURES The October 7, 2023, terror attack on Israel.
MEAN OUTCOMES AND MEASURES Changes in the numbers of overall calls and suicide-related calls to the ERAN helpline using an interrupted time-series analysis.
Results: RESULTS. Analysis indicated that overall calls increased significantly on October 7. However, the number of suicide-related calls in the 3 months before October 7 was 1,887, whereas 1,663 suicide-related calls were registered in the 3 months after. The percentage of suicide-related calls decreased significantly on October 7 and gradually increased in the following period.
Conclusions: CONCLUSIONS AND RELEVANCE The findings suggest that although short-term emotional distress increased after national trauma, the percentage of suicide-related calls decreased. These results support previous studies suggesting that suicidality is not one of the immediate reactions to such traumas

Prevalence of suicide in adolescents and youth at Ultra High Risk for Psychosis - A Systematic Review and Meta-Analysis

S. H. Ang[1]*, S. Venkateswaran[1], K. N. C. Naidu[2,3], M. Bakulkumar Goda[1] and G. Kudva Kundadak[2,4,5]

[1]Yong Loo Lin School of Medicine, National University of Singapore; [2]Department of Psychological Medicine, National University Hospital; [3]Saw Swee Hock School of Public Health, National University of Singapore; [4]Department of Psychological Medicine, Yong Loo Lin School of Medicine, National University of Singapore and [5]Department of Psychological Medicine, Alexandra Hospital, Singapore, Singapore
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.340

Introduction: Suicide remains a major risk factor for individuals suffering from Schizophrenia. Recent studies have established that patients in the prodromal Schizophrenia state (i.e. Ultra High Risk for Psychosis) also experience significant rates of suicidal ideation and behaviour. However, less is known about the prevalence of suicidality among the adolescent and youth UHR population, a demographic particularly vulnerable to the psychosocial and environmental risk factors of psychosis.
Objectives: This review aims to synthesise the existing literature on the prevalence of suicidal ideation and behaviour in the adolescent and youth at Ultra High Risk for Psychosis (UHR), and the relevant associations between suicidality and its correlates.
Methods: The databases PsycINFO, PubMed, Embase, Cochrane Library, Web of Science and Scopus were accessed up to July 2024. References within selected journals were further handsearched for eligible articles. Keywords and controlled vocabulary used consisted of: ('Ultra High Risk' OR 'At Risk Mental State' OR 'Clinical High Risk') AND ('Schizophrenia' OR 'Psychosis') AND ('Self-Harm' OR 'Suicide' OR 'NSSI') AND ('Adolescent' OR 'Youth'). Articles that included participants with an established diagnosis of schizophrenia or intellectual disability, history of frank psychotic episodes and extended use of antipsychotics were excluded. A meta-analysis of prevalence was subsequently performed for lifetime suicidal ideation, lifetime non-suicidal self-injury, lifetime suicidal attempt and current suicidal ideation. A narrative review was also carried out for the correlates of suicidality amongst the adolescent and youth UHR population.
Results: Fourteen studies were included in this meta-analysis. Meta-analysis revealed a high prevalence of lifetime suicidal ideation (56%), lifetime non-suicidal self-injury (37%), lifetime suicidal attempt (25%) and current (2-week) suicidal ideation (58%).

Narrative review revealed that personal transition to psychosis and positive family history of psychosis was strongly associated with suicidal attempt, while CAARMS (Comprehensive Assesment of At Risk Mental States) severity score was associated with suicidal ideation. Depression was strongly associated with both suicidal attempt and suicidal ideation, whereas positive symptoms and self-disturbance were associated with self-injury.
Conclusions: The prevalence of suicidal ideation and behaviour among UHR adolescent and youth is high and comparable to the general UHR population. Effective detection and management of suicide risk will be especially crucial in the adolescent UHR population. Existing measures that mitigate suicide risk in the general UHR population should be adopted for the youth and adolescent context.

Trends in antipsychotic polypharmacy and potential overtreatment with antipsychotics- We are not there yet!

S. Crutzen[1,2*], S. Gangadin[3], K. H. Hua[4] and S. Castelein[1,5]

[1]Lentis Research, Lentis; [2]Psychosis Department; [3]Rob Giel Research Center, University Medical Center Groningen, Groningen; [4]Apotheek Spaarne Gasthuis, Spaarne Gasthuis, Haarlem and [5]Faculty of Behavioural and Social Sciences, University of Groningen, Groningen, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.341

Introduction: Due to the potentially severe side effects of antipsychotics, overtreatment is an important concern. Previous research focussed on antipsychotic polypharmacy and excessively high doses.
Objectives: In this study, the aim is to map trends in potential overtreatment, antipsychotic polypharmacy, total antipsychotic dose and the subjective side effect burden. Moreover, the association of the total antipsychotic dose and antipsychotic polypharmacy with the subjective side effect burden will be investigated.
Methods: Data from a large (n>5000) naturalistic longitudinal cohort was used (PHAMOUS, 2013-2021). Potential overtreatment was defined as a total antipsychotic dose equivalent to >5mg risperidone, in combination with a high subjective side effect burden. Mixed effect models were used to investigate trends in potential overtreatment, antipsychotic polypharmacy, total antipsychotic dose and the subjective side effect burden. A mixed effect model was used to assess the association of total antipsychotic dose and antipsychotic polypharmacy with total subjective side effect burden.
Results: Overall, 15,717 observations nested in 5,107 patients were used. About one-third of patients were potentially overtreated, with no change over time. The prevalence of a dose above the equivalent of 5 mg risperidone decreased over time, while antipsychotic polypharmacy prevalence increased. The total subjective side effect burden slightly decreased. A higher dose and antipsychotic polypharmacy was associated with a higher subjective side effect burden.
Conclusions: The subjective side effect burden did decrease the last decade. This might be caused by lower doses and more adequate use of polypharmacy. Still, the overtreatment rate is about one-third and the subjective side effect burden is still high. To reduce the subjective side effect burden and overtreatment, addressing inappropriate antipsychotic polypharmacy remains prudent.

Functional outcome in psychotic and affective inpatients: role of cognitive function

E. I. Maihofer[1], G. Sachs[2] and A. Erfurth[1,2*]

[1]1st Department of Psychiatry and Psychotherapeutic Medicine, Klinik Hietzing and [2]Medical University of Vienna, Vienna, Austria
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.342

Introduction: Functional outcome is a central clinical concern in inpatient psychiatry. Neurocognition is known to be an important factor in achieving a good functional outcome.
Objectives: We have previously investigated whether cognitive dysfunction improves over the course of inpatient treatment, where acutely admitted patients are offered a combination of pharmacological treatment and cognitive remediation (Maihofer et al. J Clin Med 2024, 13, 4843). We now investigate the extent to which the functional outcome of patients with psychotic and affective disorders is associated with cognitive function over time.
Methods: Adult inpatients aged 18-66 years (female = 57.9%, male = 42.1%) were assessed with the Screen for Cognitive Impairment in Psychiatry (German version, SCIP-G: Sachs et al. Schiz Res Cogn 2021, 25, 100197; Sachs et al. Schiz Res Cogn 2022, 29, 100259). According to ICD-10 research criteria, 83 patients received an F2 diagnosis (schizophrenia, schizoaffective and delusional disorders), 61 patients met the criteria for bipolar disorder or mania (F30/F31) and 90 for depression (F32/F33). All patients received state-of-the-art pharmacotherapy and cognitive remediation using the COGPACK® software package version 6.06. Functioning was assessed using the Global Assessment of Function (GAF).
Results: SCIP scores at baseline correlate significantly with SCIP scores at time point two (r=.74, p<.001). The SCIP at baseline is significantly correlated with patients' functional level (r=.32, p=.01). The higher the baseline SCIP score, the higher the GAF score (r=.33, p=.01). The higher the GAF score at baseline, the higher the SCIP score at time 2 (r=.26, p=.039). The higher the SCIP score at time 2, the higher the GAF score at time 2 (r=.42, p<.001).
Conclusions: During their stay in hospital, acutely admitted patients improved in function and neurocognition, regardless of their diagnostic classification. Functionality as measured by the GAF correlates significantly with cognitive ability as assessed by the SCIP-G.

Efficacy of Yoga in Treating Positive and Negative Symptoms of Schizophrenia and Enhancing Social Functioning: A Systematic Review and Meta-Analysis of Randomized Controlled Trials

M. L. Geremias[1], A. Victoria de Vasconcelos[2], A. L. Balduino de Souza[3], I. Borja De Oliveira[4], I. Santos Raposo Andrade[5], V. M. Soares Campos[6] and D. Soler Lopes[7]*

[1]Medicine, University of Joinville Region (UNIVILLE), Joinville; [2]Medicine, Afya College of Medical Sciences of Santa Inês, Santa Ines; [3]Medicine, Evangelical University of Goias, Anapolis; [4]Medicine, University of São Paulo, São Paulo; [5]Medicine, Pontifícia Universidade Católica de Campinas, Campinas; [6]Medicine, Federal University of Santa Catarina (UFSC), Florianópolis, Brazil and [7]Medicine, Lancaster University, Lancaster, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.343

Introduction: Schizophrenia is a chronic mental disorder marked by positive symptoms such as hallucinations and delusions, and negative symptoms such as social withdrawal and apathy. While traditional pharmacological treatments effectively manage positive symptoms, they often fall short in addressing negative symptoms and social functioning. Yoga has emerged as a complementary therapy that may help improve both. However, its overall impact remains uncertain.
Objectives: This review aims to synthesize evidence on yoga's effectiveness in reducing positive and negative symptoms of schizophrenia and enhancing social functioning.
Methods: A systematic search was conducted in Scopus, Web of Science, and PsycINFO in September 2024, following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. Included studies were peer-reviewed randomized controlled trials (RCTs) assessing yoga's effects on symptom severity and social functioning in schizophrenia. A fixed-effects or random-effects model was applied, with subgroup analyses performed. Standard mean differences (SMDs) and mean differences (MDs) were used for effect size estimation.
Results: Sixteen RCTs were included, involving 862 participants. Yoga (n = 393) was compared to three control groups: treatment-as-usual (n = 152), other physical activities (n = 124), and waitlist (n = 193). Yoga significantly reduced overall symptom severity relative to control, as shown by a decrease in PANSS scores (MD = -6.61, 95% CI -13.21 to -0.0, p = 0.05, I^2 = 82%). It significantly improved positive symptoms relative to waitlist (SMD = -0.87 [-1.70, -0.03]) and treatment-as-usual (SMD = -0.65 [-1.21, -0.09]), with effects comparable to those observed with physical activity (MD = -1.30 [-3.09, 0.49]). There were no significant effects on negative symptoms, with SMDs of -1.59 [-4.18, 1.01] for the waitlist and -1.16 [-2.41, 0.09] for treatment-as-usual, and a MD of -1.32 [-3.60, 0.97] when compared to physical activity outcomes. Additionally, yoga did not significantly impact social functioning, showing SMDs of -0.44 [-1.56, 0.68] for the waitlist and -0.44 [-2.29, 1.41] for treatment-as-usual, and a MD of 2.30 [-0.74, 5.34] for physical activity.
Conclusions: This review shows that yoga is effective in reducing overall symptom severity compared to controls and improves positive symptoms relative to treatment-as-usual or waitlist, but not compared to physical activity. There were no significant differences in alleviating negative symptoms or enhancing social functioning. These findings suggest yoga may be a promising adjunctive treatment for positive symptoms of schizophrenia, especially when traditional treatments are insufficient. Further high-quality RCTs with standardized protocols are needed to confirm these results and establish optimal treatment parameters.

Investigation of DRD2, NRG1 and PI3K/AKT/MTOR Expression Levels Before and After Antipsychotic Treatment in Female Patients with Schizophrenia

O. Sehitogullari[1]*, Ç. Ozulu[2], T. D. Berkol[1] and A. E. Bayrak[3]

[1]Psychiatry, Health Sciences University Bakirkoy Prof. Dr. Mazhar Osman Mental Health and Neurological Diseases Training and Research Hospital, Istanbul; [2]Moleculer Biology and Genetics, Istanbul University, Istanbul and [3]Medical Genetics, Istanbul University, Istanbul Faculty of Medicine, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.344

Introduction: Schizophrenia, affecting about 1% of the global population, is marked by positive, negative, and cognitive symptoms, leading to significant disability and a shortened lifespan due to physical health issues. Early intervention is crucial, as untreated psychosis can persist. This study examines changes in mRNA expression in the NRG-1/PI3K-AKT and DRD2 pathways in treated and untreated patients, hypothesizing that expression decreases and varies with treatment.
Objectives: We aim to assess the impact of antipsychotic treatment on the expression levels of the PI3K/AKT/m-TOR signaling pathway, linked to the neurodevelopmental hypothesis of schizophrenia, and associated with the dopaminergic DRD-2 and glutamatergic NRG-1 systems. This study will examine mRNA expression of DRD-2, NRG-1, and PI3K/AKT/m-TOR in leukocytes from female schizophrenia patients before and after treatment. The findings may enhance our understanding of schizophrenia's pathogenesis, identify potential genetic markers, and clarify the molecular effects of antipsychotic drugs.
Methods: Our study includes 25 healthy female volunteers and 25 female schizophrenia inpatients from Bakırkoy Prof. Dr. Mazhar Osman Mental Health and Neurological Diseases Training and Research Hospital. These inpatients met the experiment criteria, had not received treatment in the last 3 months, and were diagnosed with schizophrenia spectrum disorder according to DSM V criteria. After obtaining written consent, a sociodemographic form was completed. The Positive and Negative Symptom Scale (PANSS) was administered to eligible patients. Blood samples for DRD-2, NRG-1, and PI3K/AKT-1/mTOR mRNA expression analysis were collected from patients with PANSS scores of 95 or above before treatment and after scores decreased to 58 or below. Expression levels were determined by RT-PCR.
Results: In untreated schizophrenia patients, NRG-1 mRNA expression was significantly lower, while PI3K and mTOR mRNA expressions were significantly higher compared to the healthy control group, with no change in AKT-1 mRNA expression as shown in **Table 1**. Compared to healthy controls, treated patients

showed increased NRG-1 mRNA, unchanged PI3K and AKT-1 mRNA, and decreased mTOR mRNA as shown in **Table 2**. In treated patients, NRG-1 mRNA expression was significantly higher, and PI3K and mTOR mRNA expressions were significantly lower compared to untreated patients, with no change in AKT-1 as shown in **Table 3**. DRD-2 mRNA expression was undetectable in all groups.

Image 1:

Table 1 The Comparison of Initial Measurement of Patient Gene Expression Values with the Control Group

		Mean	SD	p
AKT-1	Patient	,493	1,73	,313
	Control	,890	,912	
NRG-1	Patient	,329	1,46	**,033**
	Control	,997	,612	
PI3K	Patient	7,310	2,67	**,000**
	Control	2,669	1,89	
mTOR	Patient	1,729	,591	**,009**
	Control	1,118	,447	

Note: p: Independent Samples T-test. N: 25 for each group

Image 2:

Table 2 The Comparison of Final Measurement of Patient Values with the Control Value

		Mean	SD	p
AKT-1	Patient	,650	1,53	,052
	Control	,890	,912	
NRG-1	Patient	1,647	0,58	**,003**
	Control	,997	,612	
PI3K	Patient	3,226	3,77	,054
	Control	2,669	1,89	
mTOR	Patient	,639	,87	**,020**
	Control	1,118	,447	

Note: p: Independent Samples T-test. N: 25 for each group

Image 3:

Table 3 The Comparison of Changes in Patient Values

	First Measurement		Final Measurement		p
	Mean	SD	Mean	SD	
AKT-1	,493	1,73	,650	1,53	,086
NRG-1	,329	1,56	1,647	0,58	**,000**
PI3K	7,310	2,67	3,226	3,77	**,000**
mTOR	1,729	0,59	,639	0,87	**,001**

Note: p: Significance value of the Paired Samples T-test

Conclusions: NRG-1, PI3K, and mTOR may contribute to schizophrenia pathogenesis, with NRG-1 and mTOR serving as potential genetic biomarkers. Antipsychotics affect molecular pathways, but not AKT-1, and DRD-2 is not expressed in immune cells.

Effects on Neurocognition of Theta Burst Transcranial Magnetic Stimulation in Patients with Resistant to Treatment Depression

Y. Cañada Perez[1]*, S. Albert[2], R. Roca[3], A. Sabater[1], P. Benavent[1], J. Ribes[1] and P. Sierra[1,4]

[1]Psychiatry and Psychology, La Fe University and Polytechnic Hospital; [2]Psychiatry, Dr Peset University Hospital, Valencia; [3]Psychology, Lluis Alcanyis Hospital, Xativa (Valencia) and [4]Medicine, University of Valencia, Valencia, Spain

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.345

Introduction: Cognitive dysfunction has been identified as a key mediator of functional impairment in major depression and a contributing factor to antidepressant resistance. Theta burst stimulation (TBS) is a novel form of transcranial magnetic stimulation (TMS) that has shown greater efficacy and efficiency than conventional TMS in the treatment of treatment-resistant depression (TRD). However, its effects on cognitive symptoms in depression remain largely unstudied.

Objectives: The objective of this study is to evaluate the impact of TBS on neurocognition in unipolar and bipolar TRD patients treated at a public hospital. Additionally, clinical, demographic, and treatment predictors of cognitive change were explored.

Methods: This is a follow-up study of n=64 patients with TRD (unipolar=48, bipolar=16) who received daily adjunctive TBS for 6 weeks. Cognitive performance was assessed before and after TBS using different versions of the Screening for Cognitive Impairment (SCIP-S), which measures immediate verbal learning, working memory, verbal fluency, delayed verbal learning, and processing speed. Cognitive performance in each domain was compared using paired t-tests. Global cognitive change was assessed by quantifying pathological domains at baseline and at the end of TBS. Differences in neurocognition between clinical responders (50% reduction on the HDRS) and non-responders to TBS were compared using ANOVA models. Additionally, possible predictors of cognitive change in each domain were explored using correlation analyses and multiple linear regressions, which included factors such as age, diagnosis, number of TBS sessions, treatment type, TBS modality (left unilateral vs. bilateral), clinical response, and baseline severity.

Results: Patients treated with TBS achieved significant clinical response (68%) and cognitive improvement in the domains of immediate verbal learning, working memory, verbal fluency, and processing speed (mean differences of 2.16, 2.31, 1.30, and 1.05, respectively). Neurocognitive improvement was independent of clinical response. The percentage of improvement on the HDRS was only associated with improvement in the verbal fluency domain ($p = .007$). Left unilateral TBS and bipolar diagnosis predicted better global cognitive improvement in SCIP in regression models ($p = .042$, $p = .037$, respectively).

Conclusions: The results support the utility of TBS in treating cognitive dysfunction associated with TRD. Further larger studies are needed to clarify clinical and treatment predictors of cognitive improvement.

Maternal antenatal depression is associated with metabolic alterations that predict birth outcomes, neurodevelopment and mental health of the child

P. Girchenko[1,2]

[1]Clinical Medicine Research Unit, MRC Oulu, University of Oulu, Oulu and [2]Deoartment of Psychology, University of Helsinki, Helsinki, Finland
doi: 10.1192/j.eurpsy.2025.346

Introduction: Evidence regarding metabolic alterations associated with maternal antenatal depression (AD) is limited, and their role as potential biomarkers improving the prediction of AD and adverse child birth, neurodevelopmental, and mental health outcomes remains unexplored.
Objectives: To identify metabolic measures associated with AD.
To test whether the metabolic measures associated with AD increased the amount of variance explained in AD over its risk factors.
To test whether the identified metabolic measures increased the amount of variance explained in child gestational age and weight at birth, developmental milestones at ages 2.3-5.7 years and any mental or behavioral disorder by the ages of 13.1-16.8 years over AD, sex, and age.
To replicate the findings in an independent cohort.
Methods: In a cohort of 331 mother-child dyads, we applied elastic net regression to study associations between AD (history of medical register diagnoses and/or Center of Epidemiological Studies Depression Scale score during pregnancy≥20) and 95 metabolic measures analyzed three times during pregnancy. Child birth and mental health outcomes were extracted from national registers and child neurodevelopmental outcomes were mother-reported.
Results: Elastic net regression identified 15 metabolic measures that collectively explained 25% ($p<0.0001$) of variance in AD, including amino and fatty acids, glucose, inflammation, and lipids. These metabolic measures increased the variance explained in AD over its risk factors (32.3%,$p<0.0001$ vs. 12.6%,$p=0.004$), and in child gestational age (9.0%,$p<0.0001$ vs. 0.7%, $p=0.34$), birth weight (9.0%,$p=0.03$ vs. 0.7%, $p=0.33$), developmental milestones at the age of 2.3-5.7 years(21.0%,$p=0.002$ vs. 11.6%,$p<0.001$) and any mental or behavioral disorder by the age of 13.1-16.8 years (25.2%,$p=0.03$ vs. 5.0%,$p=0.11$) over AD, child sex and age. These findings replicated in the independent cohort.
Conclusions: AD is associated with alterations in 15 metabolic measures, which collectively improve the prediction of AD over its risk factors, and birth, neurodevelopmental and mental health outcomes of the child over AD. These metabolic measures may become biomarkers identifying at-risk mothers and children for personalized interventions.

Difficult-to-Treat Depression: Effectiveness, Functionality, and Quality of Life—Preliminary Results from a Real-World Prospective Cohort under Esketamine Treatment in Spain after 3-Month Follow-Up

M. Gomez Revuelta[1*], G. Cortez Astudillo[2], J. Sastre Yáñez[3], D. Gutiérrez Hormaechea[4], P. Fuentes Pérez[3], C. Ovejas Catalán[3], J. L. Victores Barcia[3], M. Fernandez Rodriguez[2] and N. Vargas Berni[5]

[1]Psychiatry, IDIVAL, Santander; [2]Sierrallana Hospital, Torrelavega; [3]IDIVAL; [4]Hospital Universitario Marqués de Valdecilla, Santander and [5]HU Reina Sofía, Cordoba, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.347

Introduction: Major depressive disorder (MDD) is one of the most prevalent and disabling mental health conditions globally. Approximately one-third to half of MDD patients, suffer from difficult-to-treat depression (DTD), a condition marked by persistent symptoms that do not respond to multiple standard treatments. DTD is often associated with comorbid physical and psychiatric conditions leading to chronic disability and a reduced quality of life. The complexity of DTD poses a considerable challenge in clinical practice, underscoring the need for innovative treatment options.
Objectives: Despite the demonstrated efficacy of esketamine in controlled clinical trials, real-world evidence is limited. This study aimed to address this gap by assessing the effectiveness of esketamine in routine clinical practice in DTD patients.
Methods: This prospective, naturalistic, open-label, observational study was conducted at Marqués de Valdecilla University Hospital in Cantabria, Spain. It included 33 patients diagnosed with DTD, comprising both unipolar and bipolar depression, as well as persistent depressive disorder (see table 1). Esketamine was administered intranasally in doses ranging from 56 mg to 84 mg, across three phases: induction, consolidation, and maintenance. Treatment effectiveness was measured using the MADRS, Clinical Anxiety Scale (CAS), and Clinical Global Impression (CGI). Functionality and quality of life were assessed with the Brief Functioning Scale (FAST) and the EQoL-5D (ESH). Assessments were conducted at baseline, 1-month, and 3-month. Data analysis was performed using SPSS v26, with repeated measures ANOVA and Pearson's χ^2 tests employed to evaluate changes over time.
Results: The final analysis included 33 patients with DTD and long-lasting current MDD episodes (table 2). Baseline MADRS scores indicated severe depression (39.12 ± 6). Significant reductions in MADRS scores were observed at both one month (21.61 ± 11.15) and 3-month (19.70 ± 11.65) compared to baseline. At 3-month, 54.5% of patients achieved a ≥50% reduction in MADRS scores, and 30.3% reached remission (MADRS < 12). Similar improvements were seen in anxiety (CAS) and health status (ESH) scores, with significant reductions noted over time.

However, functional improvements (FAST) were not statistically significant (see table 3).
Conclusions: Esketamine demonstrated substantial effectiveness in reducing both depressive and anxiety symptoms in DTD patients over three months. More than half of the patients achieved a significant reduction in depression severity, with nearly a third reaching remission. The presence of late responders suggests that esketamine may benefit those initially unresponsive to treatment. These findings support esketamine as a valuable therapeutic option for DTD in real-world clinical settings.

doi: 10.1192/j.eurpsy.2025.348

Introduction: Major depression not only impairs individual health and labour market performance but also imposes significant economic burdens on society. It is linked to substantial costs through healthcare use, lost productivity and absenteeism. Recent genome-wide association studies have identified genetic markers associated with major depression, offering new insights into its genetic risk factors. However, the potential association of these genetic risks with educational attainment and career outcomes remains underexplored. Understanding this connection is crucial for addressing the broader public health and socio-economic implications of depression risk beyond clinical populations.
Objectives: This study aims to investigate the relationship between genetic risk for depression and individual career performance in the general population of Finland from 1992 to 2017.
Methods: We utilised pooled data from the Finnish Finrisk (1992-2012) and FinHealth (2017) studies, which together include a population representative sample of individuals aged 25-64 (N=20,121). Genetic, survey and socio-economic registry data were integrated for this analysis. Using probit and semi-structural regression models, we examined various career performance indicators, with polygenic scores for depression (Howard *et al.* Nat Neurosci 2019; 22 343-352) as the main explanatory variable. Socio-demographic characteristics and genetic principal components were included as controls.
Results: Our study revealed a negative association between higher genetic risk for depression and the likelihood of attaining higher education—an essential predictor of career success. Additionally, our study provides novel insights into how elevated polygenic risk for depression was linked to employment and self-employment rates, both directly and via educational pathways.
Conclusions: These findings highlight that genetic predispositions for depression can adversely affect career prospects in the general population, suggesting that the economic burden of depression extends beyond those clinically diagnosed. As effect sizes are modest, our results imply that supportive measures and compensatory behaviours could mitigate some of the educational and career disadvantages associated with higher genetic risk for depression.

doi: 10.1192/j.eurpsy.2025.349

Introduction: Major depressive episodes (MDEs) occur in mood disorders such as major depressive disorder (MDD) and bipolar disorder (BD), affecting nearly one in four U.S. adults over their lifetime. The neurotrophic hypothesis suggests that disruptions in growth factor signaling contribute to MDEs. While brain-derived neurotrophic factor (BDNF) is well-studied, vascular endothelial growth factor (VEGF) may also play a crucial role, though evidence of its association with MDEs is inconsistent. Understanding VEGF is important for identifying predictors of treatment outcomes, such as those related to electroconvulsive therapy (ECT). This study explores the relationship between VEGF and MDEs, focusing on implications for ECT effects.
Objectives: To consolidate evidence from studies evaluating the association between VEGF and ECT outcomes in patients experiencing an MDE.

Methods: A systematic search for published clinical trials and cohort studies was conducted on August 13, 2024, using keywords including ECT, VEGF, MDE, and mood disorders, with no language or publication date restrictions. We selected studies enrolling patients in a current MDE related to MDD or BD, excluding those focused on manic episodes. A fixed-effects or random-effects model was applied. Subgroup analyses were performed to investigate the data further.
Results: Seven studies involving 621 participants (61.9% female; mean age: 50.2 years) were preselected. Six studies measured plasma VEGF levels; one assessed cerebrospinal fluid (CSF) levels. Plasma VEGF levels did not differ significantly between healthy controls and MDE patients, either before (SMD = 0.02 [−0.17; 0.21], p = 0.84, I^2 = 0%) or after ECT (SMD = 0.11 [−0.21; 0.44], p = 0.50, I^2 = 0%). Of the five studies reporting post-ECT VEGF levels, three found a significant increase from baseline. A significant correlation was observed between baseline plasma VEGF levels and depression response to ECT (r = 0.34, Z = 4.92, p < 0.0001, I^2 = 0%). Of the five studies examining increased VEGF levels after ECT and symptom reduction, only one found a significant association. A sensitivity analysis indicated substantial heterogeneity when including the CSF study.
Conclusions: Plasma VEGF levels were not significantly different in MDE patients compared to healthy controls, either before or after ECT. Baseline plasma VEGF levels positively correlated with ECT treatment response, suggesting they may provide neurotrophic support and predict outcomes. Despite robust findings and minimal heterogeneity, this analysis was limited by the low number of studies and small sample sizes. Further research is needed to explore the association between MDEs and VEGF, especially in the CSF, and to clarify the role of baseline VEGF in ECT treatment response.

doi: 10.1192/j.eurpsy.2025.350

Introduction: Anxious depression (AxD) as an independent diagnostic has been controversial, with many suggesting it as a transient state and others highlighting evidence of a worse outcome, severity, and increased suicide risk. The International Classification of Diseases (ICD-11) lists a related concept under 6A73, Mixed depressive and anxiety disorder. Previous literature on ketamine's efficacy has mainly focused on either anxiety or depression, with limited comparison of both groups. Given their high comorbidity and shared pathophysiology, we aimed to assess ketamine's efficacy in these populations.
Objectives: This meta-analysis aimed to consolidate evidence from clinical trials evaluating ketamine therapy in AxD and Non-Anxious Depression (NAxD).
Methods: A search for published clinical trials in indexed journals and databases was conducted on August 11, 2024. Keywords included ketamine, anxiety, comorbidity, and depression, with no restrictions on language or publication date. Studies on bipolar or psychotic depression were excluded. A random-effects model accounted for variability, and subgroup analyses were performed.
Results: Eight studies involving 536 participants (mean age = 39.0 years) were preselected. Seven studies defined "anxious depression" as a score of 7 or higher on the HAMD-AS, with AxD mean of 8.74 (±0.56) and NAxD mean of 5.83 (±1.9). MADRS scores were 35.18 (±2.22) for AxD and 31.97 (±2.29) for NAxD. The effect size of improvement in depressive symptom severity (as assessed by the MADRS) was not significantly different between the groups either 13 days after treatment (SMD = -0.07[-0.69, 0.55], p = 0.82, I2 = 73%) or 26-28 days after treatment (SMD = -0.30[-0.64, 0.04], p = 0.09, I2 = 21%). The overall depression response also did not significantly differ between the groups (odds ratio = 0.84 [0.50, 1.41], p = 0.52, I^2 = 13%). Insufficient data were available for remission rates.
Conclusions: Ketamine shows comparable efficacy in reducing depressive symptoms and achieving response in both groups. The group classified as AxD parallels previous reports of increased severity when reviewing baseline scores MADRS and other available scores. Thus, ketamine should be considered a viable treatment for patients with AxD, as they may have lower response rates to traditional antidepressants. This analysis was limited by the small number of studies, small sample sizes, and moderate heterogeneity. Differences in baseline depressive symptom severity and varying definitions of MDD with anxiety also constrained our analysis. Given the severity of symptoms in this population, we recommend developing better classification instruments for AxD. Further research is needed to explore remission differences in AxD and refine treatment strategies.

The 'time' in lifetime: age-stratification and its impact on immune-based depression treatment

E. Van Assche[1]*, C. Hohoff[1] and B. T. Baune[1,2,3]

[1]Department of Psychiatrie, University of Münster, Münster, Germany; [2]Department of Psychiatry, University of Melbourne and [3]Department of Psychiatry, The Florey Institute of Neuroscience and Mental Health, Melbourne, Australia

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.351

Introduction: Depression is increasingly linked to immunological processes. Therefore, immune-based therapies, e.g., celecoxib, are being tested as augmenting treatment strategies. Many physiological processes during life are also linked to immunological changes. We tested the hypothesis that age affects treatment efficacy in a randomized controlled sample treated with the anti-inflammatory agent Celecoxib.

Objectives: We test the combined role of age and an anti-inflammatory augmentation treatment for treatment response in depression. For a more in depth understanding we investigated the role of six methylation-based cell-types in these immunological processes in a second step.

Methods: 113 individuals with a diagnosis of major depressive disorder were included in our analyses (M_{age}=44, 56% women, M_{MADRS}= 27.7). All patients were treated with Vortioxetine and recruited stratified by high sensitive C-Reactive Protein (hsCRP; <= 3 vs. > 3 mg/L)> 3mg/L). Based on a randomized controlled design, augmentation with Celecoxib was administered to 55 patients. A second assessment was performed after 6 weeks of treatment ($M_{MADRS\ 6W}$= 20.2). Cell type compositions of neutrophils, monocytes, B-cells, CD4+ and CD8+ Lymphocytes, and natural killer cells (NK), were estimated based on epigenome-wide DNA methylation markers (Illumina Infinium MethylationEPIC 850k BeadChip) using the Houseman method. Analyses were performed with linear regression models with $MADRS_{6W}$ as outcome. Our hypothesis was tested in the full sample. The additional analyses were performed stratified by age. All models were corrected for sex, hsCRP, and depression severity at baseline.

Results: Our analysis showed a statistically significant interaction between age and treatment condition on depression outcome (p=0.040), with significant main effects for both variables in the model (intervention: p=0.045, age: p=0.022). Sex and hsCRP were no statistically significant contributors. The intersection was identified at 45.5 years. Younger individuals treated with celecoxib showed a more pronounced reduction in MADRS ($M_{reduction}$=-9.6), than older individuals treated with the same condition ($M_{reduction}$=-5.5). The stratified individuals younger than 45 years, showed that neutrophils were associated with better treatment outcome (p=0.028), whereas for individuals older than 45 years this was the case for B-cells and NK cells (p=0.011, and p<0.001, respectively).

Conclusions: Our results indicate that immunological profiles in depression and in relation to treatment may be age-dependent, which can have major consequences for treatment success with anti-inflammatory augmenting strategies. Replication in an independent sample is needed to confirm the role of age in immune-focused treatment strategies for depression.

A randomized controlled trial of supervised group exercise therapy in patients with clinical depressive and anxiety disorders: the challenge of patient compliance

Q. Zhai[1,2]*, M. Folkesson[3], C. Hörnsten[4], J. Persson[5,6], S. Montgomery[1,7,8] and Y. Freund-Levi[1,9,10,11]

[1]School of Medical Sciences, Örebro University; [2]Department of Psychiatry, Örebro University Hospital; [3]School of Health Sciences, Örebro University, Örebro; [4]Department of Clinical Sciences, Psychiatry, Umeå University, Umeå; [5]School of Behavioural, Social and Legal Sciences, Örebro University, Örebro; [6]Department of Neurobiology, Care Sciences and Society; [7]Clinical Epidemiology Division, Department of Medicine Solna, Karolinska Institutet, Stockholm, Sweden; [8]Department of Epidemiology and Public Health, University College London, London, United Kingdom; [9]Department of Clinical Science and Education, Södersjukhuset, Karolinska Institutet, Stockholm; [10]Department of Geriatrics, Örebro University Hospital, Örebro and [11]Department of Geriatrics, Södertälje Hospital, Södertälje, Sweden

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.352

Introduction: Depression and anxiety are global mental health concerns and contribute significantly to the global burden of human disease. Although psychotherapies and antidepressant drugs are effective and commonly used treatments for depression and anxiety, some patients do not achieve full remission of their symptoms and there remains a risk of residual symptoms.

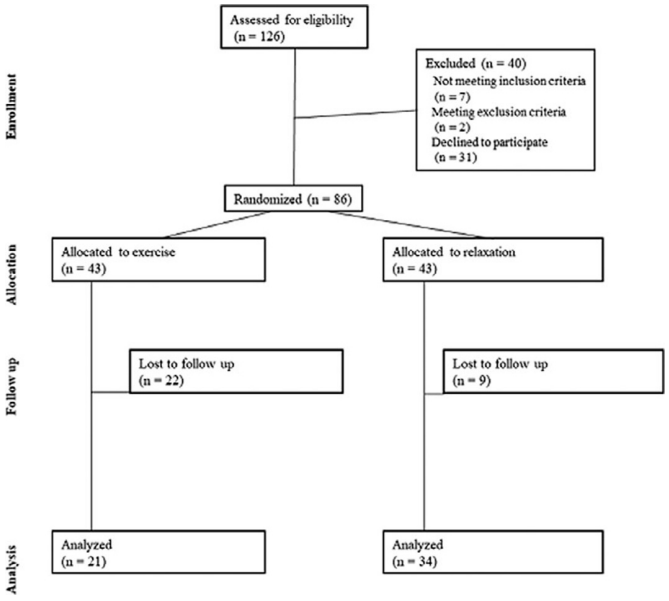
Objectives: To validate effect of supervised group exercise therapy in outpatient treatment of depressive and anxiety disorders.

Methods: A total of 126 individuals were screened for elevated depressive and anxiety symptoms. 86 participants aged between 18 and 65 years (Median=33 years; IQR 15; 62.8 % females) were randomly assigned to exercise group (EX, N=43) or relaxation group (REL, N=43). EX was planned to receive 36 sessions and REL 12 sessions during a 12-week intervention. Depressive

symptoms were measured using Montgomery-Åsberg Depression Rating Scale (MADRS and MADRS-S) and anxiety symptoms using Becks Anxiety Inventory (BAI) at pre-, mid- and post-intervention.
The study is registered on ClinicalTrials.gov Register for RCT's (NCT04714528).

Results: Intention-to-treat analyses showed that both groups improved significantly in depressive and anxiety symptoms (MADRS: EX from 24.5±7.4 to 15.8±8.3 points, REL from 22.8 ±6.4 to 16.6±7.8 points. MADRS-S: EX from 27.6±7.2 to 19.6±8.1 points, REL from 26.3±7.1 to 18.7±9.5 points. BAI: EX from 25.0 ±12.2 to 16.4±9.9 points, REL from 24.3±12.4 to 17.0±12.6 points). However, there was no statistically significant difference between the groups in the degree of improvement. In addition, there was a high and differential attrition rate (51.2 % in EX vs 20.9 % in REL, p=0.007). It took longer than expected for the exercise group to finish the intervention (EX 19.2±5.1 weeks vs REL 14.8 ±4.0 weeks). Attrition analysis showed that individuals that had student as their main occupation were more likely to drop out and participants with sleep medication were more likely to adhere to interventions.

Image 1:



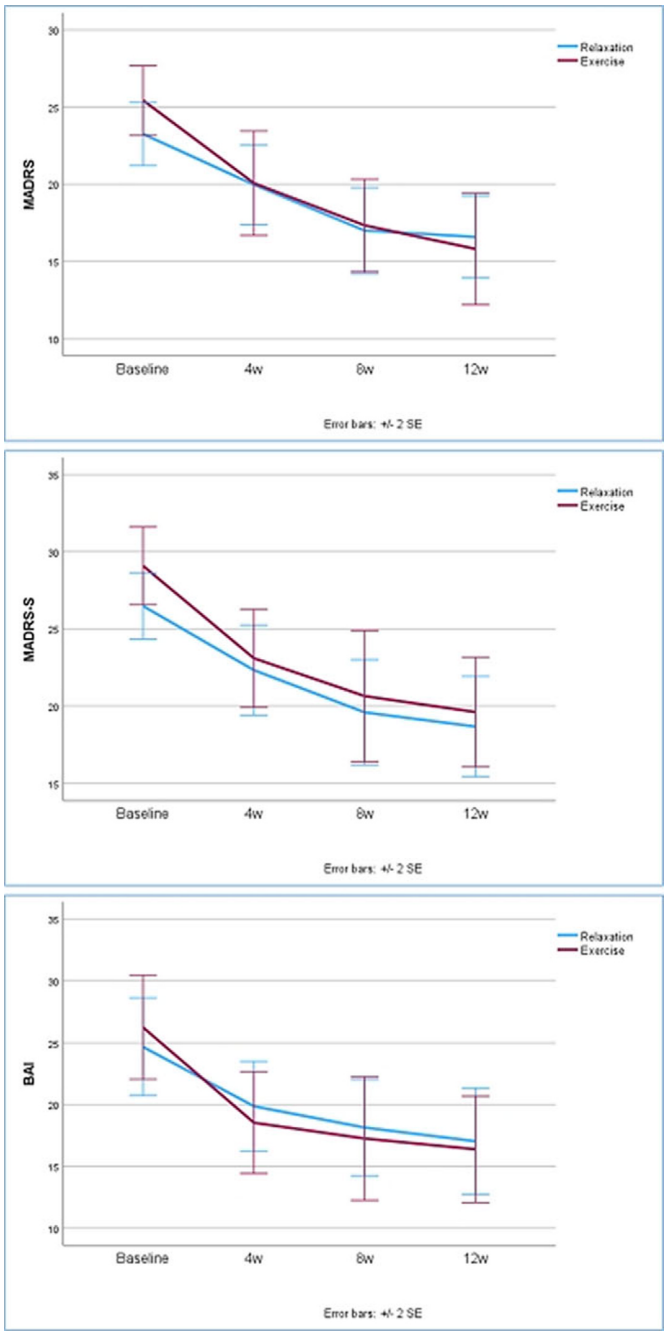


Image 2:

Conclusions: The study reflects the challenges of outpatient, activity-based treatments for mild to moderate depressive and anxiety disorders regarding compliance, despite great efforts were made to keep the participants' motivation throughout the study. Although both groups improved in depression and anxiety symptoms similarly, due to the lack of control group with no active treatment, it is difficult to assess possible placebo effect from this study. The differential bias from attrition and compliance makes it difficult to draw definitive conclusions.

Mapping the exposome of mental health: exposome-wide association study of mental health outcomes among UK Biobank participants

A. Arias[1]*, L.-K. Pries[1], B. D. Lin[1,2] and S. Guloksuz[1,3]

[1]Department of Psychiatry and Neuropsychology, School for Mental Health and Neuroscience, Maastricht University Medical Centre, Maastricht, Netherlands; [2]Department of Preventive Medicine, Institute of Biomedical Informatics, Bioinformatics Center, School of Basic Medical Sciences, Henan University, Kaifeng, China and [3]Department of Psychiatry, Yale University School of Medicine, New Haven, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.353

Introduction: Mental disorders result from a complex interplay of genetic and environmental factors. However, the multiplicity of exposures and the complexity of mental health phenotypes pose a major challenge. The 'exposome' paradigm offers a holistic view of the environment that contrasts traditional hypothesis-driven approach in psychiatry. Within this framework, exposome-wide studies provide a novel tool to systematically identify phenotype-exposure relationships, offering an innovative perspective to map the exposome of mental health.
Objectives: To map environmental factors associated with psychiatric diagnostic domains and symptom dimensions in the UK Biobank cohort. In this study, we aim to identify exposures unique to specific mental health outcomes, as well as those shared across conditions.
Methods: We analysed UK Biobank participants with complete Mental Health Questionnaire data (N = 157,298). Outcomes were classified as either psychiatric domains or symptom dimensions. After quality control, 294 environmental, lifestyle, behavioral, and economic variables were included. An Exposome-Wide Association Study (ExWAS) was conducted per outcome in two equally split datasets, applying Bonferroni correction for multiple testing (P < 1.70 x 10^-4). Missing exposure data was imputed using Multiple Imputation by Chained Equations. Variables associated with each outcome were then tested in a multivariable model.
Results: In diagnostic domains, ExWAS analyses identified 26 to 165 significant factors. Multivariable analysis revealed 10 to 65 significant associations, with traumatic events, physical complaints, and sleep disturbances emerging across domains. Cannabis use was associated with common psychiatric disorders (ORs: 1.10-1.79), while computer use was uniquely linked to neurodevelopmental disorders (OR = 1.23). Eating disorders showed stronger correlations with food-related exposures. In symptom dimensions, ExWAS identified 46 to 180 significant factors. Multivariable analysis revealed similar exposure groups to those in diagnostic domains. Notably, self-harm was uniquely associated with childhood adoption (OR = 1.39).
Conclusions: This comprehensive mapping of exposome revealed that several factors, particularly in the domains of those previously well-studied were shared across mental health phenotypes, providing further support for transdiagnostic pathoetiology. Our findings also showed that distinct relations might exist. Continued exposome research through multimodal mechanistic studies guided by the transdiagnostic mental health framework is required to better inform public health policies.

Cognitive Development in Children of Mothers with Hypertensive Disorders During Pregnancy: Findings from the ALSPAC Study

B. Dachew[1]*, G. Ayano[1] and R. Alati[1]

[1]School of Population Health, Curtin University, Perth, Australia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.354

Introduction: While the immediate physical health consequences of hypertensive disorders during pregnancy are well-documented, their potential impact on children's mental health and cognitive outcomes remains relatively under-investigated. Research exploring the link between hypertensive disorders during pregnancy and cognitive function has yielded conflicting findings. Some studies report associations, while others fail to establish a link or even suggest a protective effect. Many of these studies have focused on children with intrauterine growth restriction, low birth weight, small for gestational age, and/or preterm births—factors already known to influence cognitive development. Furthermore, almost all of this research focuses on early childhood, leaving a critical gap in our understanding of the long-term effects into adolescence, a period characterised by rapid cognitive development and academic achievement.
Objectives: This study aimed to examine the associations between hypertensive disorders during pregnancy and intelligence quotient (IQ) in children at the ages of 8 and 16 years.
Methods: Our study sample comprised participants in the Avon Longitudinal Study of Parents and Children (ALSPAC) cohort, an ongoing population-based longitudinal birth cohort in Bristol, Avon, United Kingdom. Children's IQ was measured using the Wechsler Intelligence Scale for Children (WISC-III). This study included over 4900 and 3300 mother-child pairs at ages 8 and 16, respectively. Binary and multinomial logistic regression analyses were used to estimate odds ratios for the associations.
Results: Hypertensive disorders of pregnancy (gestational hypertension and/or pre-eclampsia) were not found to be associated with lower IQ scores in children at ages 8 and 16. In the multinomial logistic model, we found children born to mothers with gestational hypertension but not pre-eclampsia were more likely to have above-average IQ at age 16 compared to average IQ children born to mothers without gestational hypertension (OR = 1.42; 95% CI: 1.03 – 1.94). This association did not persist when children with below-average IQ were used as the reference category in the analysis, and no such associations were also observed at the age of 8 years.
Conclusions: Our findings revealed no evidence of associations between hypertensive disorders during pregnancy and lower IQ scores in children ages 8 and 16. The observed association between gestational hypertension and higher odds of having an above-average IQ at age 16 needs further investigation. Our findings were

based on a cohort study with a longer follow-up period, offering a higher level of evidence than previous studies. The consistency of our findings across different developmental stages strengthens the validity of our results and suggests that any potential effects of hypertensive disorders during pregnancy on cognitive function may be limited or transient.

Adolescence in the Digital Age the Influences of Smartphone and Social Media Use on a Cohort of Irish Teenagers

F. Donnelly[1]

[1]National Health Service Improvement, Health Service Executive, Dublin, Ireland
doi: 10.1192/j.eurpsy.2025.355

Introduction: The aim of this study was to investigate the associations between smartphone and social media use and mental health outcomes among adolescents in Ireland.
Objectives: This study aimed to fill a gap in the existing literature by examining specific types of online activity, such as cyberbullying and "sexting" (sending sexually explicit messages), and the independent associations of these activities with worse mental health.
Methods: This study is a cross-sectional analysis of secondary data from the 2023 Planet Youth Partner survey. The study population was 4,544 mostly 15- and 16-year olds from Cavan, Monaghan and North County Dublin. The dependent variable was the total Strengths and Difficulties Questionnaire (SDQ) score, a tool commonly used to assess mental health status. Independent variables included hours of social media use, experiences of cyberbullying, body image perceptions, and involvement in sexting. Multivariable logistic regression models were employed to determine the associations between these variables and mental health outcomes, controlling for potential confounders such as gender, sleep duration, and maternal education level.
Results: The study found significant associations between several online activities and worse mental health. High use of social media (4 hours per day or more) was associated with a 62% greater risk compared to those who used it for about 1 hour or less.
Cyberbullying was a also strong predictor of poor mental health, with victims nearly twice as likely to have a high SDQ score. Negative perceptions of one's own body image and participating in sexting were also significantly associated with worse mental health outcomes.
Gender differences were observed, with females more likely to be victims of cyberbullying, to be asked for and to send sexually explicit messages, and to have worse mental health outcomes when compared to males. Insufficient sleep was also a significant predictor, with those sleeping for 6 hours or less per night having more than twice the risk compared to those who slept for the recommended 8 hours or more.
Conclusions: The findings of this study suggest that specific aspects of smartphone and social media use, particularly high usage and negative online experiences, are independently associated with poorer mental health outcomes in adolescents. These results are consistent with international evidence and highlight the need for targeted public health interventions to mitigate the risks associated with this technology. The study recommends developing evidence-based guidelines for parents and teachers to promote healthier online behaviours among adolescents in Ireland. It also calls for a national Public Health campaign and policy measures to enforce stricter regulations on social media companies and protect young people from harmful online experiences.

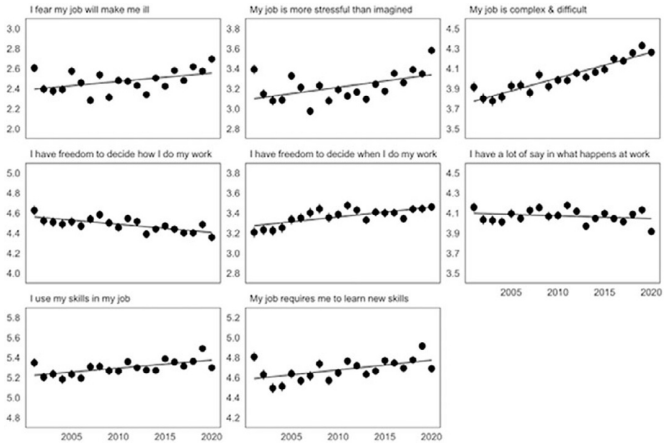
The Workplace Mental Health Paradox - Why is mental ill health at work rising yet we have never spent more to prevent it?

N. Glozier[1]*, R. Morris[1], M. Deady[2] and S. Harvey[2]

[1]University of Sydney and [2]Black Dog Institute, Sydney, Australia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.356

Introduction: There is a prevailing paradox in workplace mental health. Never has so much been spent on prevention, intervention, and regulatory programs yet the prevalence of employee mental ill-health has not only not improved, but rates are seemingly on the increase.
Objectives: Two evaluate 2 explanations (a) has the reported prevalence of specific psychosocial workplace risk and protective factors changed over the last two decades (e.g., is work getting more stressful), and (b) are there trends, and generational differences, in the impact of these factors on worsening or buffering mental health (e.g., are employees becoming less resilient).
Methods: We use a 20 year population based cohort study (n=19,744).
(a) We estimated the linear trend over time (2001 to 2020), to determine the population-trends of reporting higher levels of job demands, control and complexity.
(b) To assess cohort differences in resilience to job stressors we estimated regression models predicting mental health (MHI-5 scores) by each psychosocial risk and birth cohort. Each model included the interaction between the self-reported psychosocial risk factor (independent variable) and birth-cohort (moderator variable) to estimate the dependency for each cohort. The marginal slope between the level of the risk factor and mental health for each cohort was estimated by the delta method (see below). Differences between the marginal slopes of adjacent cohorts were tested with adjustment for pairwise comparisons.
Results: From 2000 to 2020 employees report trends of increased perceived job demands and decreasing autonomy in deciding how work was completed, but increasing control over when work is carried out and greater skill use(fig 1). High levels of demands have a stronger negative impact on the mental health of Millenailas than older cohorts at a similar age, and this younger cohort benefits less from the buffering effect of autonomy at work imporving mentla health (fig2).

Image 1:



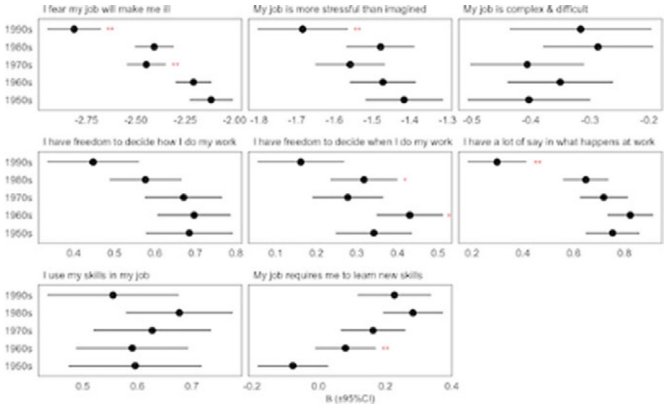


Image 2:

Conclusions: Over the last 20 years, employees report increasing job demands and decreasing freedom in deciding how work was completed, but increasing control over when work is carried out. Although this reflects, in part, an age effect as both demands and control peak in middle age, more recent cohorts also report higher demands and less control at any given age. In addition, the marginal negative impact of higher levels of job demands on mental health has increased in younger cohorts, alongside reducing psychological benefits from autonomy and control compared with older cohorts. This combination of employees viewing work as becoming more stressful and younger employees increased sensitivity to work stress effects may explain part of the paradox and have major implications for employers, insurers, regualtors and benefit systems.

Decline in alcohol use among the general Czech population – role of young adults?

L. Kážmér[1]* and L. Csémy[1]

[1]National Institute of Mental Health, Klecany, Czech Republic
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.357

Introduction: Alcohol consumption, monitoring its prevalence and temporal trends, is one of the leading epidemiological interests in public health. When there are significant changes over time, understanding these new trends is crucial for health professionals. In the Czech Republic, a significant and sustained decline in alcohol use among the adolescent population has been observed since the mid-2010s (Kážmér & Orlíková *Adiktologie.* 2017; 17(2):118–132; Kážmér & Csémy *J Public Health Res.* 2019; 8(1):1493). The decline was in line with general trends across Europe and North America (Kraus *et al. Addiction.* 2018; 113(7):1317–1332). However, the factors driving the decline were attributed to new modes of adolescent leisure activities (Chomynová & Kážmér *J Subst Use.* 2019; 24(6):630–637) rather than changes in prevention-related issues (Pennay *et al. Drug Alcohol Rev.* 2018; 37(S1):S115–S119). If the decline among the adolescent population has continued into later age groups, there should also be a significant decline in today's Czech young adults.
Objectives: The study examines temporal trends in alcohol use in the general population of the Czech Republic, with an age-specific focus on young adults under 25 years of age.
Methods: Time series of nationally representative data on alcohol use were compiled from the National Survey on Tobacco and Alcohol Use in the Czech Republic. The large-sample representative survey, conducted annually by the National Institute of Public Health, provided high-quality data on alcohol use among the general Czech population aged ≥15 years in 9 cross-sectional time periods: 2012, 2014, 2016, 2018–2023. The subgroup of respondents aged 15–24 years was selected. Time trends for three main measures on alcohol use were considered: i) mean annual alcohol consumption (in litres per person per year); ii) prevalence of binge drinking (%); iii) prevalence of abstainers (%).
Results: Among the Czech population aged 15–24, all the three measures on alcohol use have improved in recent time periods. In particular, the estimated mean annual alcohol consumption decreased significantly from 8.9 litres (95% CI: 6.5–11.2) of pure ethanol per person per year in 2012 to 5.1 litres (95% CI: 4.0–6.2) in 2023. The prevalence of last year abstainers increased accordingly: from 8.6% (95% CI: 5.4%–12.8%) in 2012 to 13.1% (95% CI: 8.6%–17.6%) in 2023. In a similar vein, there was also an improvement in the prevalence of binge drinking.
Conclusions: There was a noticeable decrease in alcohol use among the Czech young adults aged 15–24 years in recent periods, especially after 2020. Further research will be conducted to examine this trend in more detail.
Funding: The study was supported by the Operational Program Johannes Amos Comenius, project number CZ.02.01.01/00/22_008/0004583.

Social isolation and risk of schizophrenia: a cohort and Mendelian randomization study

Q. Wu[1], Y. Nie[1], J. Zhang[1] and Y. Y. Liang[1]*

[1]Center for Sleep and Circadian Medicine, The Affiliated Brain Hospital of Guangzhou Medical University, Guangzhou, China
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.358

Introduction: Social isolation refers to the lack of objective social contact and is one of the health risk factors. Previous studies have shown that social isolation is associated with several physical and mental disorders. However, the relationship between social isolation and schizophrenia remains unclear.
Objectives: This study aimed to investigate whether there is a potentially causal association between social isolation and schizophrenia.
Methods: The UK Biobank (UKB) is a large population-based cohort study. In this study, social isolation was assessed using self-reported questionnaires. Participants were categorized into socially isolated and non-isolated groups based on the scores. We identified cases of schizophrenia through hospitalization records and death registrations in the UKB. Propensity score matching was used to reduce the influence of confounding factors. We estimated the hazard ratios (HRs) of social isolation to schizophrenia using Cox regression. In addition, we estimated the causal association between social isolation and schizophrenia by two-sample Mendelian randomization analysis. Genetic data for social isolation and schizophrenia were extracted from the UKB and the Psychiatric Genomics Consortium, respectively.
Results: 315 cases of schizophrenia were documented during a mean follow-up of 12.3 years. After adjusting for demographic, socioeconomic, and lifestyle factors, the risk of schizophrenia in the socially isolated group was 1.73 times higher than that in the non-socially isolated group (95% CI, 1.37-2.18). Results from two-sample Mendelian randomization analysis showed that participating in more other group activities was associated with a reduced risk of schizophrenia (OR, 0.49; 95% CI, 0.31-0.77).
Conclusions: Social isolation was potentially causally associated with an increased risk of schizophrenia. The results of this study emphasize the importance of reducing the risk of developing schizophrenia through initiatives to reduce social isolation and increase social activities.

Adolescent cannabis use and young adult healthcare use in a population-based birth cohort linked to healthcare administrative records

P. Martinez[1]*, M.-C. Geoffroy[1], C. Temcheff[2], S. Côté[3], R. Tremblay[4,5], M. Boivin[6] and M. Orri[7]

[1]Department of Psychiatry, McGill Group for Suicide Studies, Douglas Mental Health University Institute; [2]Department of Educational and Counselling Psychology, McGill University; [3]École de Santé Publique, University of Montreal, Montreal; [4]Research Unit on Children's Psychosocial Maladjustment, Québec, Canada; [5]School of Public Health, Physiotherapy, and Sports Science, University College Dublin, Dublin, Ireland; [6]Department of Psychology, Université Laval, Quebec and [7]Department of Psychiatry, McGill Group for Suicide Studies, Douglas Mental Health University Institute, Montreal, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.359

Introduction: Evidence links early adolescent cannabis use (CU) to long-term health risks, but most studies lack comprehensive early-life confounder data and rely on subjective health measures.
Objectives: To assess the association between adolescent CU trajectories and healthcare use for physical and mental health problems (P&MHP) in young adulthood.
Methods: Data from the Québec Longitudinal Study of Child Development, a 23-year population-based birth cohort (N = 1,591), were linked to healthcare administrative records (hospitalizations, outpatient, and ER visits). CU trajectories (exposure) were derived from age of onset and frequency data (ages 12-17) using group-based trajectory modeling. Missing data on pre-exposure confounders were multiply imputed. Overlap-weighted logistic regression was used to assess the adjusted associations between these trajectories and healthcare use for P&MHP between ages 18-23.
Results: Three CU trajectories were identified: non-users, late users, and early users (Figure 1). Early users had a higher risk of healthcare use for any mental disorder (OR 1.55, 95% CI 1.17-2.06), common mental disorders (OR 1.69, 95% CI 1.19-2.39), substance-related disorders (OR 2.25, 95% 1.24-4.10), and hospitalizations for physical diseases (OR 1.57, 95% CI 1.03-2.38) compared to non-users. No significant differences were found between late and non-users.

Image 1:

Conclusions: These findings highlight the need for targeted interventions during adolescence to mitigate long-term health risks. Prevention efforts should prioritize early users, and be focused on integrated social, mental, and physical care.

Maternal depression around pregnancy and risk of mental disorder among offspring: a population-based cohort study with sibling comparison

A. Nevriana[1]* and D. Lu[1]

[1]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.360

Introduction: Previous studies have indicated a potential increase in risks of mental disorders among the offspring of mothers with depressive disorders. However, the association between maternal exposure at different developmental periods, including the period around pregnancy, and the offspring's risk for adverse mental health outcomes remain unclear. Additionally, there is a lack of studies controlling for potential confounding by familial factors.
Objectives: To determine the association between the timing of maternal depression around pregnancy and the risk of mental disorders among the offspring.
Methods: Population-based cohort study using linkage from Swedish national registers including 4,051,192 live singleton births in 1973-2010. Individuals were followed from age 3 until the first date of mental disorders diagnosis, emigration, death or 31 December 2013. We included the following diagnoses: depression, postpartum depression, neurotic disorders, stress-related disorders, alcohol use disorders, drug use disorders, attention deficit hyperactivity disorder (ADHD), autism spectrum disorder (ASD), intellectual disability, behavioural disorders (child-/adolescent-onset), schizophrenia, other psychotic disorders, bipolar disorders, eating disorders, personality disorders, and others. Timing of maternal depression was defined as the earliest date of diagnosis or antidepressant dispensation around pregnancy, categorised into '1 year before conception', 'during pregnancy', and '1 year after childbirth.' Hazard ratios (HR) were estimated using Cox regression, adjusting for potential confounders. We also stratified the associations by age at follow up and birth year. To account for familial confounding, comparison was also made within full siblings.
Results: In the population-based analysis, maternal depression was associated with a higher risk of overall mental disorder diagnosis in offspring in all three time periods, although the association tends to be stronger during the first year before conception (HR 1.90, 95% CI 1.78-2.03) and somewhat attenuated afterwards (HR during pregnancy 1.77, 95% CI 1.69-1.84; HR 1 year after childbirth 1.68, 95% CI 1.57-1.79; Figure 1). However, the associations were attenuated to null in the sibling analysis (HR overall mental disorders 1 year before conception 0.94, 95% CI 0.83-1.07; during pregnancy 1.08, 95% CI 0.98-1.17; 1 year after childbirth 1.00, 95% CI 0.88-1.13). Similar patterns were observed in most mental disorder diagnoses (Figure 1), across age at diagnosis (Figure 2), and birth year (Figure 3).

Image 1:

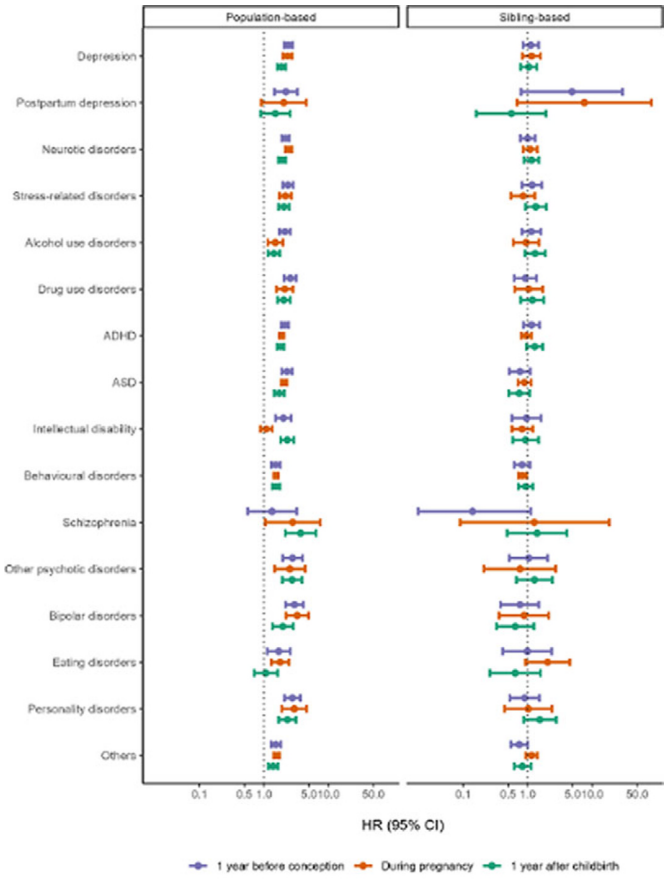

Figure 1 Association between maternal depression around pregnancy and risk of mental disorders among offspring. Adjusted for maternal age, parity, smoking, body mass index, offspring sex. For population-based analysis, estimates were further adjusted for maternal country of birth, education, cohabitation status, offspring birth year.

Image 2:

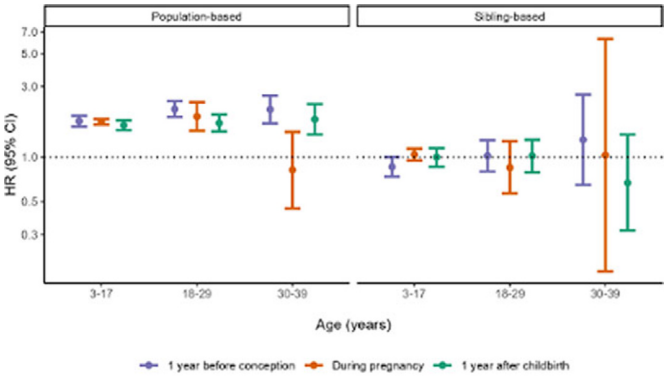

Figure 2 Association between maternal depression around pregnancy and risk of any mental disorders among offspring, stratified by age at follow up. Adjusted for maternal age, parity, smoking, body mass index, offspring sex. For population-based analysis, estimates were further adjusted for maternal country of birth, education, cohabitation status, offspring birth year.

Image 3:

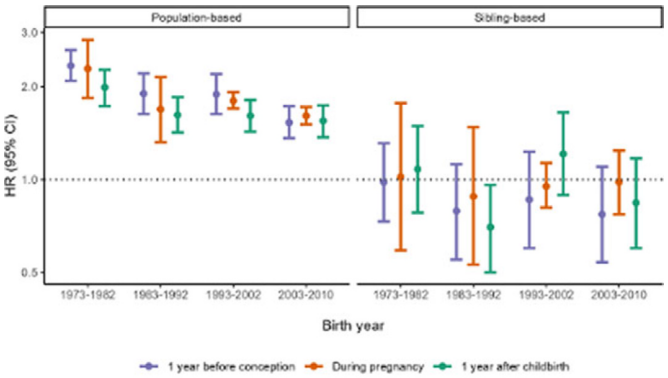

Figure 3 Association between maternal depression around pregnancy and risk of any mental disorders among offspring, stratified by birth year. Adjusted for maternal age, parity, smoking, body mass index, offspring sex. For population-based analysis, estimates were further adjusted for maternal country of birth, education, cohabitation status, offspring birth year.

Conclusions: While maternal depression before, during, and after pregnancy is predictive for the offspring's mental health development, the link is likely driven by shared familial genetic and environmental factors.

Four Major Psychiatric Disorders in Childhood and Early Adulthood and Siblings' Subsequent Socioeconomic Status: A Nationwide Familial Coaggregation Cohort Study

W. Yang[1]*, K. Komulainen[1], R. Niemi[1], M. Gutvilig[1], P. Böckerman[2], M. Elovainio[1] and C. Hakulinen[1]

[1]University of Helsinki and [2]Labour Institute for Economic Research LABORE, Helsinki, Finland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.361

Introduction: Previous studies show the aggregation of major psychiatric disorders (MPDs; a combined category of schizophrenia, bipolar disorder, depression, and anxiety) among siblings. However, few studies have examined whether MPDs in childhood and early adulthood are associated with siblings' future socioeconomic status (SES).
Objectives: To assess subsequent SES outcomes among siblings of individuals with an MPD diagnosed at age 5–25.
Methods: This cohort study included 54,742 full siblings, 4,490 paternal, and 4,858 maternal half siblings of individuals born in Finland between 1975–1985 with MPDs diagnosed at ages 5–25 (affected probands). We defined the reference groups as identical types of siblings of individuals without any MPD diagnosis (matched unaffected probands). The siblings of both the affected and the unaffected probands were followed from the diagnosis date of affected probands until December 31, 2020. MPD diagnoses were obtained from the Finnish Care Register. SES was measured through employment status, annual disposable income (measured in EUR), and educational achievement derived from the FOLK module of Statistic Finland. Conditional logistic regression, median regression, and Generalized Estimating Equations (GEE) models were applied to estimate the adjusted associations.
Results: The median age (interquartile range, IQR) at baseline was 20 years (16–24) for full siblings, 17 years (12–26) for maternal half-siblings, and 18 years (12–26) for paternal half-siblings of the affected and unaffected probands. Compared to siblings of the unaffected probands, the odds of unemployment were 50% higher (95% CI: 1.46-1.55) in full siblings of affected probands with any MPD; this association was particularly pronounced in full siblings of an affected proband diagnosed before age 15 (aOR: 1.68, 95% CI 1.49-1.90). Full siblings of the affected probands were more likely not to attain a university degree (aOR: 1.37, 95% CI 1.33-1.41). The median annual disposable income was 1,518.3 EUR lower (95% CI: -1647.4, -1389.3) in full siblings of affected probands. Similar but weaker associations were observed in maternal and paternal half-siblings. For example, compared with the half siblings of the unaffected probands, the odds of unemployment were 29% (95% CI 1.16-1.44) and 23% (95%CI 1.10-1.38) higher in maternal and paternal half-siblings of affected probands with any MPD, respectively.
Conclusions: Our findings suggest that the unfavorable socioeconomic consequences of MPDs might extend to siblings.

Risk factors for treatment resistance among women with postpartum depression

Y. Chen[1]* and D. Lu[1]

[1]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.362

Introduction: Postpartum depression (PPD) impacts millions of new mothers worldwide, and the challenge of treatment resistance (TR) further hampers recovery prospects. The occurrence of TR in women with PPD and the risk factors for TR remain less studied. Identifying these factors is critical for the precise prediction of treatment responses, enabling tailored interventions and effective management of PPD.
Objectives: This study aimed to determine the prevalence of TR and assess risk factors associated with TR in women with PPD in a nationwide population-based setting.
Methods: We conducted a nationwide register-based cohort study of all women who gave birth during 2006-2021 in Sweden and were diagnosed with PPD up to 12 months postpartum. TR is defined as having ≥3 distinct antidepressant drugs, add-on medications, electroconvulsive therapy, or repetitive transcranial magnetic stimulation in one year after PPD diagnosis. Information on demographics, pregnancy characteristics and outcomes, comorbidities, and treatments were obtained from national registers. Potential risk factors in relation to TR were assessed using multivariable Poisson regression.

Results: Out of 58 618 women with PPD (mean age 30.8, SD 5.3), 4 933 (8.5%) occurred treatment resistance. Younger age (<20 vs. 25-29y: risk ratio (RR) 1.28, 95% CI 1.07-1.52), lower educational level (<9 vs. >12y: 1.52, 1.39-1.67), lower family income level (lowest 20% vs. top 20%: 1.28, 1.16-1.40), smoking at early pregnancy (≥10 cigarettes/day vs. no smoking: 1.39, 1.19-1.62), prior physical comorbidities (Charlson comorbidity index ≥2 vs. 0: 1.40, 1.18-1.65), prior psychiatric disorders (RRs for specific types range: 1.54-6.04) were significantly associated with treatment resistance. In contrast, non-primiparous patients had a reduced risk of treatment resistance (vs. primiparous women, RRs for 2 parities: 0.74, 0.69-0.79; ≥3 parities: 0.87, 0.80-0.95). Maternal body mass index, snuff use, delivery method, pregnancy outcomes, and hypertensive or diabetic disorders did not predict treatment resistance.
Conclusions: Treatment resistance in women with PD is common and is notably associated with specific demographic and clinical profiles. These findings highlight the need for personalized management strategies, particularly for identified high-risk groups.

Bridging the gap in mental health knowledge and gender-based violence interventions: findings from a mixed-methods study in Moldova

V. Condrat[1]* and J. Chihai[2]

[1]Trimbos Moldova and [2]Mental Health, Moldova State University of Medicine and Pharmacy, Chisinau, Moldova, Republic of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.363

Introduction: This study examines the intersection of mental health services and gender-based violence (GBV) in Moldova, identifying knowledge gaps and assessing service capacity through a mixed-methods approach, including focus groups and a national KAP survey. The findings highlight the urgent need for specialized training and evidence-based interventions to improve mental health outcomes and GBV responses.
Objectives: The study aimed to develop targeted interventions and training programs to enhance the capacity of mental health professionals in Moldova to address mental health challenges and gender-based violence (GBV) by identifying knowledge gaps, assessing practices, and providing actionable insights for improved service delivery and outcomes.
Methods: The study used a mixed-methods design, combining quantitative surveys and qualitative focus groups to assess knowledge gaps and training needs among mental health professionals in Moldova. A cross-sectional survey gathered quantitative data on perceptions of knowledge gaps, confidence, and training needs from a representative sample of professionals, including CCSM coordinators. Focus group discussions, held on the same day, provided qualitative insights into their challenges and suggestions for service improvement. This approach offered both breadth and depth, leading to evidence-based recommendations for addressing the identified gaps in knowledge and training.
Results: The study uncovered major knowledge gaps among mental health professionals in Moldova, particularly in psychopharmacology, child and geriatric psychiatry, and gender-based violence (GBV) management. These gaps, identified via surveys and focus groups, reflected a lack of confidence in applying modern protocols and navigating legal aspects. There was a strong call for continuous professional development, especially through structured training in underserved regions. Inadequate training negatively affected the quality of care, particularly in GBV cases, though professionals were eager to improve their skills despite regional disparities in resources. The findings underscore the need for targeted training and better resource allocation.
Conclusions: The study concluded that mental health professionals in Moldova face significant knowledge gaps, particularly in psychopharmacology, child and geriatric psychiatry, and managing gender-based violence (GBV). These gaps, along with insufficient training, negatively impact care quality, especially for GBV cases. Despite motivation to improve, professionals face challenges like limited access to updated training and regional disparities in resources, highlighting the need for structured, continuous training and equitable resource distribution to improve mental health services nationwide.

Prevention and treatment of psychosis in pregnant and/or postpartum women with known psychiatric illness – the state of the art of clinical practice guidelines

A. L. Falcão[1]*, B. S. Leal[2], I. M. Figueiredo[2], A. S. Lourenço[2], G. Soares[2], M. Nascimento[2], C. Oliveira[2] and J. Reis[1]

[1]Hospital Júlio de Matos, Unidade de Saúde Local de São José, Clínica 2 and [2]Hospital Júlio de Matos, Unidade de Saúde Local de São José, Clínica 3, Lisboa, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.364

Introduction: Motherhood represents a challenge for all women, but it's even more complex for those suffering from serious psychiatric illnesses such as Bipolar Disorder, Schizophrenia and Schizoaffective Disorder. The treatment of these women requires special care during the preconception, prenatal and postnatal phases, taking into account the risk of decompensation, the psychosocial factors involved and the difficult balance between the potential harm to the foetus and/or infant and the risks associated with not treating the mother. With the scarcity of randomised clinical trials and limited evidence, clinical practice guidelines become essential to determine the best therapeutic approaches to adopt.
Objectives: To systematise the best evidence of care for pregnant and/or postpartum women with a history of psychotic illness.
Methods: Systematic literature review.
Results: Mental health management in women with severe psychiatric illness who want to become pregnant should involve shared decision-making and multidisciplinary counselling. In women of childbearing age who are diagnosed with such conditions, adequate awareness of the illness and the need for family planning is the first step towards effective and safe long-term treatment. In the prenatal period, it's essential to monitor early signs of relapse, to psychoeducate about the need to stop comorbid consumption and to carry

out additional foetal ultrasounds at specific times to rule out malformations in foetuses exposed to antipsychotics and lithium. In the postnatal period, the risk of relapse is especially high. Careful monitoring in the first month after birth and regular review thereafter are essential. When necessary, hospitalisation in mother-baby units is the *gold standard* treatment. Pharmacological treatment of pregnant and breastfeeding women should weigh up the risks associated with non-intervention and the potential adverse effects on the foetus and lactating infant. The choice of psychotropic drugs should taking into account the varying safety profiles; for example, typical antipsychotics can cause extrapyramidal symptoms or withdrawal syndrome in the newborn and atypical antipsychotics metabolic syndrome. Nevertheless, despite the quality of the evidence, antipsychotics appear to be generally safe in pregnancy and breastfeeding.
Conclusions: The management of mental health care for this subpopulation must ensure that decisions are shared, follow-up is multidisciplinary, pre- and post-natal monitoring is individualised and pharmacological treatment is chosen based on the best balance between the needs of the mother and the safety of the foetus/infant.

Neurodevelopmental Consequences of Antenatal Exposure to Antipsychotic Medication: A Systematic Review

A.-S. Rommel[1]*, T. Robakis[1], C. Kaplan[1] and E. Poels[2]

[1]Psychiatry, Icahn School of Medicine, New York, United States and [2]Psychiatry, Erasmus MC, Rotterdam, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.365

Introduction: Antipsychotic (AP) medications are increasingly prescribed, with indications ranging from psychotic illness to mood disorders. Many patients and clinicians are concerned about long-term consequences of drug exposure in the neurodevelopmentally critical prenatal window. Yet maternal mental illness itself is also associated with significant changes to the prenatal environment.
Objectives: To systematically review the literature on the short- and long-term behavioral, socioemotional, psychomotor, and neurocognitive outcomes in children prenatally exposed to AP medication.
Methods: We included original studies assessing cognitive, motor, behavioral, social, and psychiatric. Searches were performed in MEDLINE, Cochrane, Embase, and PsycINFO for studies up to March 15, 2024. Quality and risk of bias were assessed using the Newcastle Ottawa Scale (NOS). Studies were eligible for inclusion if they were original, peer-reviewed research which assessed human offspring of any age, prenatally exposed to any antipsychotic medication, regardless of maternal indication for use.
Results: We identified 1,315 studies, and reviewed 53 in full-text screening. The final synthesis included 16 studies (6 cohort and 10 register-based studies) with the number of prenatally exposed individuals ranging from 17 to >15,000.Eleven studies included a control group with maternal mental illness in at least one of their analyses. These groups varied with some including any maternal mental illness, while others used an antipsychotic discontinuation control, and still others used non-antipsychotic psychiatric medication use as a control. Five studies included only a general or healthy maternal population control. Eight studies assessed motor development, ranging from newborn assessments up to 14 years of follow-up. These studies observed early motor delays following prenatal exposure to AP medication, which did not persist into later childhood. Five studies investigated risk for neurodevelopmental diagnoses and three studies explored school performance following prenatal AP exposure. No significant associations were found after adjustment for confounding. The quality of the evidence ranged from moderate to high.
Conclusions: While the majority of studies did not identify differences between exposed and unexposed groups, some differences emerged early in infancy or when looking at neurodevelopmental disorders. However, our findings suggest that the observed neurodevelopmental differences are likely due to confounding by indication rather than exposure to antipsychotics themselves. More rigorous research is needed to clarify the neurodevelopmental effects of AP use during pregnancy.

Coping Experiences of Trans Women throughout their Gender-Affirmation

G. Yıldız Aytaç[1]*, D. Hiçdurmaz[1] and K. Başar[2]

[1]Psychiatric Nursing Department, Hacettepe University Faculty of Nursing and [2]Department of Psychiatry, Hacettepe University Faculty of Medicine, Ankara, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.366

Introduction: Trans women can encounter various struggles throughout their gender-affirmation. There is a need for further understanding of trans women's experiences to gain deeper insights into how they cope throughout this process. The development of psychosocial support services that are adapted to their personal needs is crucial to enhancing their coping strategies.
Objectives: The current study aimed to examine the coping experiences of trans women throughout their gender-affirmation.
Methods: This qualitative descriptive study utilized in-person, semi-structured interviews with 12 trans women to gather in-depth data on their coping experiences. Content analysis was employed to analyze the data.
Results: The experiences of trans women emerged in five themes. Four themes correspond to four distinct phases: "self-discovery," "self-acceptance," "coming out to others," and "after coming out to others," each characterized by its own coping mechanisms. The fifth theme was labeled "to facilitate coping…". Trans women have a heightened need for support during the periods "when they confront the possibility that their situation will not change," "when they accept themselves but attempt to decide how they can move forward in life," and "when they first come out to people around them." The study indicates the critical role of addressing family and social stigma in trans women's coping throughout their gender-affirmation. Furthermore, the study unveils a striking finding that efforts to facilitate trans women's coping throughout their gender-affirmation extend beyond the purview of mental health

professionals. It reveals that these efforts have dimensions that concern the entire healthcare system, the legal system, social security, labor, and working conditions.
Conclusions: The study highlights the importance of psychosocial support and improved access to these services to bolster trans women's coping mechanisms throughout their gender-affirmation, with particular emphasis on the specific periods identified above. The psychosocial support for trans women should encompass not only them but also extend to their families, significant others, and the community in which they live, adopting a holistic approach.

Bidirectional relationship between premenstrual disorders and autoimmune disease: a nationwide register-based study in Sweden

J. Zhou[1]*, E. Bränn[1], Y. Yang[1], Y. Chen[1], M. Opatowski[1], U. A. Valdimarsdóttir[2], E. Bertone-Johnson[3] and D. Lu[1]

[1]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; [2]Faculty of Medicine, University of Iceland, Reykjavik, Iceland and [3]Department of Biostatistics and Epidemiology, School of Public Health and Health Sciences, University of Massachusetts Amherst, Amherst, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.367

Introduction: Prementrual disorders (PMD) affect millions of women in reproductive age worldwide. Understanding the potential link between PMD and its comorbidities, including autoimmune disease (AD), is crucial for ultimately improving women's health. Although hormonal fluctuations seem involved in the development of PMD and some AD, the relationship between PMD and AD remains unclear.
Objectives: Hence, we aimed to investigate the bidirectional association between PMD and AD.
Methods: Leveraging Swedish nationwide and regional registers, we conducted a nested-case control study and a matched-cohort study. Among 3,630,028 eligible women of reproductive ages during 2001-2022, we identified 104,972 incident PMD, their unaffected full sisters, and 10 unaffected matched women per case. We extracted 41 types of AD diagnosis recorded in the registers. Using conditional logistic regression and Cox regression models, we estimated the odds ratio (OR) and hazard ratio (HR) with 95% confidence interval (CI).
Results: Women with AD had a 12% increased risk of subsequent PMD (95% CI 1.10-1.15) compared to unaffected women, and a 6% increased risk compared to their unaffected full sisters (95% CI 1.01-1.11). Women with PMD had 23% (95% CI 1.20-1.26) and 17% (95% CI 1.10-1.24) elevated risks of subsequent AD compared to unaffected women and full sisters, respectively. Among parous women, a stronger bidirectional association was observed for those both exposed to PMD and perinatal depression (nested case-control OR:1.46, 95%CI 1.38-1.54; matched cohort HR:1.49, 95%CI 1.34-1.66) compared to only PMD (nested case-control OR:1.04, 95%CI 1.00-1.07; matched-cohort HR:1.14, 95%CI 1.07-1.21). The strongest bidirectional association with PMD was found for autoimmune thyroid disease and celiac disease.
Conclusions: Our findings illustrate a bidirectional association between PMD and AD, in particular among parous women with a history of perinatal depression. If confirmed in future studies, healthcare professionals need to be vigilant about the risk of AD in women with PMD and *vice versa.*

Evaluating the Impact of a Photoaging App versus School-Based Educational Intervention on Adolescents' Knowledge, and Attitudes towards Tobacco Use in Omani Public Schools: A Cluster Randomized Trial

T. Al-Mahrouqi[1]*, F. Al-Ghailani[2], M. Al-Maqbali[2], M. Al Saidi[3] and P. Gouda Parameshwara[3]

[1]Oman Medical Speciality Board; [2]Sultan Qaboos University and [3]National University of Science and Technology, Muscat, Oman
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.368

Introduction: Tobacco use among adolescents remains a significant public health concern, particularly in the Middle East region.
Objectives: This study compared the effectiveness of two interventions aimed at preventing tobacco use among Omani adolescents: the home use of photoaging app and a school-based educational module.
Methods: In this randomized controlled trial, 188 adolescents were assigned to either the photoaging app or the educational module group.
Results: The use of photoaging app demonstrated superior efficacy in enhancing perceptions of tobacco's harmful effects, with 78.5% of participants recognizing tobacco as definitely harmful compared to 27.1% in the educational module group ($p<0.001$). Additionally, the app group showed greater resistance to peer pressure, with 95.7% stating they would "definitely" refuse tobacco if offered by a friend, versus 83.5% in the module group ($p=0.031$). However, the educational module was more effective in promoting support for smoking bans in public places. While not statistically significant, the photoaging app group showed a trend towards lower susceptibility to tobacco use.
Conclusions: These findings suggest that integrating technology-driven interventions like photoaging apps with comprehensive educational programs could enhance tobacco prevention efforts among adolescents. Future interventions should consider a hybrid approach to leverage the strengths of both methods in combating youth tobacco use.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.369

Introduction: Autism Spectrum Disorder (ASD) affects approximately 3% of children and adolescents in the U.S. This condition is increasingly prevalent worldwide and presents significant treatment challenges. Preliminary evidence suggests that cannabidiol (CBD) cannabis extracts may help manage ASD symptoms, but their efficacy and potential harms have not yet been systematically investigated.
Objectives: To systematically review and meta-analyze the evidence from clinical trials investigating the efficacy and safety of CBD cannabis extracts in alleviating symptoms of ASD in children and adolescents.
Methods: We conducted a comprehensive search in MEDLINE, Embase, PsycINFO, and the Cochrane Central Register of Controlled Trials using MeSH terms including "Autism Spectrum Disorder," "Cannabidiol," "Cannabis," "Child," and "Adolescents." No language or publication date restrictions were applied. The search was last updated on September 8, 2024. We included randomized, placebo-controlled trials on the efficacy or safety of CBD cannabis extracts in children and adolescents with ASD. For outcomes with limited study data, we used a fixed-effects model. The risk of bias in the included studies was evaluated using the Risk of Bias 2 tool.
Results: Three studies met our criteria, comprising 276 participants (78.3% male; mean age 10.5 years, range 5 to 21). Interventions included orally administered CBD cannabis extracts, with tetrahydrocannabinol (THC) present in minimal amounts or in ratios of 9:1 to 20:1 CBD to THC. Dosages of CBD started at 1 mg/kg per day and were titrated up to 10 mg/kg per day. CBD cannabis extracts significantly enhanced social responsiveness (SMD = -0.75 [-1.08, -0.43], $p < 0.01$, $I^2 = 17\%$), reduced disruptive behavior (SMD = -0.36 [-0.67, -0.06], $p = 0.02$, $I^2 = 0\%$), and alleviated anxiety (SMD = -0.33 [-0.63, -0.03], $p = 0.03$, $I^2 = 59\%$). CBD cannabis extracts also improved sleep quality, without reaching statistical significance (SMD = -0.19 [-0.49, 0.11], $p = 0.21$, $I^2 = 0\%$). There was no significant difference in adverse effects between interventions and placebo (odds ratio = 2.11 [1.00, 4.46], $p = 0.05$, $I^2 = 38\%$).
Conclusions: CBD cannabis extracts appear to provide meaningful benefits for children and adolescents with ASD, showing moderate improvements in social responsiveness and small yet notable reductions in disruptive behaviors and anxiety. They do not seem to significantly increase adverse effects compared to placebo, suggesting a favorable safety profile. These findings support the potential consideration of CBD cannabis extracts in ASD treatment plans. However, the review's limitations include a small number of studies, limited sample sizes, and significant heterogeneity. Future research with larger, robust trials is needed to clarify the efficacy and safety of CBD cannabis extracts in managing ASD.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.370

Introduction: The association between prenatal acetaminophen exposure and the development of Attention Deficit Hyperactivity Disorder (ADHD) and Autism Spectrum Disorder (ASD) remains a subject of considerable debate. Despite extensive research, the evidence regarding this relationship is conflicting.
Objectives: To perform a systematic review and meta-analysis of studies comparing the incidence of ADHD and ASD in patients that were either exposed or not exposed to acetaminophen prenatally.
Methods: We systematically searched Pubmed, Embase and Cochrane Central for eligible studies up until August 2024. Only studies which included participants with a medical diagnosis of ADHD/ASD and reported acetaminophen exposure as a binary measure were included. Available summary data was extracted from published reports and pooled with a random-effects model using odds ratios (OR) with 95% confidence intervals (CI). Hazard ratios (HR) adjusted for potential confounding factors were used for sensitivity analyses. All statistical analyses were conducted utilizing Review Manager 5.4.1. PROSPERO iD:CRD42024587662.

Results: We included five studies with a total of 2,647,536 patients with ADHD (150,741) / ASD (63,726), of whom 271,126 were exposed to acetaminophen prenatally and 2,376,410 were not exposed. Prenatal acetaminophen exposure was associated with an increased risk of developing ADHD (OR 1.30; 95% CI 1.17 to 1.45; p<0.01; I2 = 73%; Figure 1) and ASD (OR 1.17; 95% CI 1.14 - 1.20; p<0.01; I2 = 0%; Figure 2). Sensitivity analyses revealed that acetaminophen exposure during the third trimester of pregnancy was associated with an increased risk of ADHD (HR 1.26; 95% CI 1.07 to 1.47; p<0.01; I2 = 0%; Figure 3), but not during first (HR 1.10; 95% CI 0.97 to 1.26; p=0.13; I2 = 0%; Figure 3) and second (HR 1.07; 95% CI 0.95 to 1.19; p=0.26; I2 = 0%; Figure 3) trimesters.

Image 1:

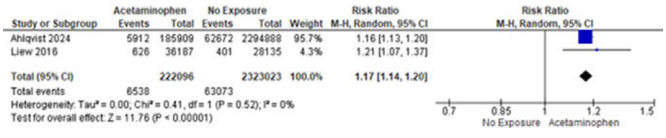

Image 2:

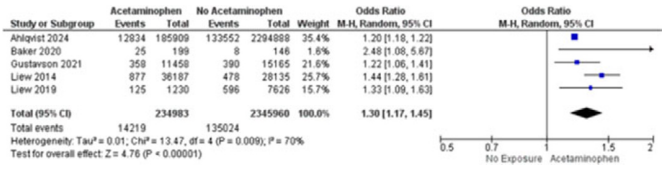

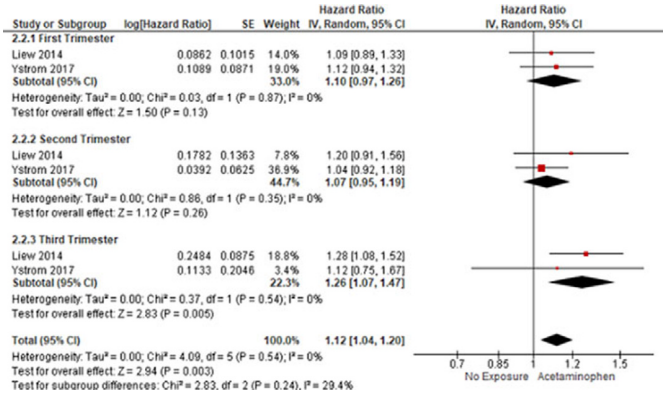

Image 3:

Conclusions: In this systematic review and meta-analysis, prenatal acetaminophen exposure was significantly associated with risk of developing ADHD and ASD, especially if exposure occurs in the third trimester of pregnancy.

The association between body dissatisfaction, depression, eating disorders and BMI: a prospective twin cohort study

I. Costantini[1]*, T. C. Eley[2], N. M. Davies[1], H. Bould[3], C. M. Bulik[4], G. Krebs[5], P. Diedrichs[6], G. Lewis[1], G. Lewis[1], C. Llewellyn[7], D. Nicholls[8], J.-B. Pingault[9] and F. Solmi[1]

[1]Division of Psychiatry, University College London; [2]Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology & Neuroscience, King's College, London; [3]Population Health Sciences, University of Bristol, Bristol, United Kingdom; [4]Department of Psychiatry, University of North Carolina, Chapel Hill, United States; [5]Research Department of Clinical, Educational and Health Psychology, University College London, London; [6]Centre for Appearance Research, University of the West of England, Bristol; [7]Department of Behavioural Science & Health, University College London; [8]Division of Psychiatry, Imperial College London and [9]Department of Clinical, Educational and Health Psychology, Division of Psychology and Language Sciences, University College London, London, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.371

Introduction: Body dissatisfaction is becoming more common among adolescents and is a putative risk factor for adverse mental (e.g., eating disorder and depressive symptoms) and physical health outcomes (e.g., excessive weight gain), both of which have also been increasing. Targeting body dissatisfaction through preventative interventions might improve these outcomes, however robust evidence of causal associations is limited.
Objectives: To investigate the association between body dissatisfaction at age 16 and eating disorder symptoms at age 21, as well as depressive symptoms and BMI at ages 21 and 26 using a co-twin control design.
Methods: We used data from the Twins Early Development Study (TEDS) and validated self-report measures. We fitted univariable and multivariable linear mixed effect models adjusting for a comprehensive list of confounding factors (Figure 1) to investigate the association between body dissatisfaction, eating disorder and depressive symptoms, and BMI in the full twin sample. We then repeated these analyses using a co-twin control design, which allows to fully and partially control for genetic confounding in monozygotic (MZ) and dizygotic (DZ) twins, respectively, and for any shared measured and unmeasured environmental factors. We conducted primary analyses in imputed datasets for participants with complete exposure data.
Results: The analytical sample included 2,183 twins (60.2% females, 61.7% DZ twins). In the full twin sample, one unit increase in body dissatisfaction at age 16 was associated with: (i) a 1.80-point increase in eating disorder symptoms at age 21 (95%CI: 1.49 to 2.11), (ii) a 0.59-point increase in depressive symptoms (95%CI: 0.46 to 0.72), and (iii) a 0.20-point BMI increase (95%CI: 0.08 to 0.32) across age 21 and 26 years. In co-twin control analyses, the association between body dissatisfaction and eating disorder symptoms was larger in DZ twins (N=661; 1.72, 95%CI: 1.11 to 2.33) than in MZ twins (N=414, 0.96, 95%CI: 0.15 to 1.77), whereas effect sizes for depressive symptoms were comparable [DZ: (0.56, 95%CI: 0.33 to 0.78); MZ: (0.50, 95%CI: 0.15 to 0.85)]. Associations with

BMI were smaller in DZ (0.20, 95%CI: 0.00 to 0.40), and null in MZ twins (0.07, 95%CI: -0.21 to 0.35).

Image 1:

	Variables	Scales/coding
Main analytic model	**Child characteristics**	
	Age at outcome	Age of the child when completed outcome
	Sex	0 females; 1 males
	Ethnicity	0 white; 1 ethnic minority
	Family characteristics	
	Composite family SES	5 different derived variables relating to parent qualifications and employment and mother's age at birth of first child
	Life events composite	The five significant life events experienced by the family at age 3
	Maternal depression	EPDS age 3 of the child
	BMI mother	BMI age 3
	BMI father	BMI age 3
	Primary confounders	
	BMI child	Standardised BMI age 14
	Puberty	Petersen Pubertal Development Scale age 12
	Autistic traits	The Autism-Spectrum Quotient (AQ) age 14
	Depressive symptoms	Short-Moods and Feelings Questionnaire (SMFQ) age 12
	Externalising behaviours	Strengths and Difficulties Questionnaire (SDQ) age 12
	Peer victimisation	Multidimensional Peer-Victimization Scale age 12
	Physical activity	Hours playing sport age 12
		Enjoyment while playing sport age 12
Sensitivity analyses	**Secondary confounders**	
	Chaos at home	CHAOS (Confusion, Hubbub and Order Scale) at home age 12
	Parenting	Parental discipline, derived from Deater-Deckard et al (1998) age 12
		Parental feelings questionnaire (PFQ) age 12
	Genetic	PRS for anorexia nervosa, PRS for schizophrenia + 10 principal components of genetic ancestry

Conclusions: Our findings suggest that greater body dissatisfaction might be a causal risk factor for eating disorders and depression in young people, as associations seen in the full sample persisted in co-twin control analyses. This indicates that body dissatisfaction could be a modifiable target to reduce the risk of these mental health problems in adolescents and young adults. Evidence of associations between body dissatisfaction and increased BMI was weaker in co-twin control analyses than in the full sample. This might be due to larger proportions of shared genetic risk and thus require larger sample sizes to detect.

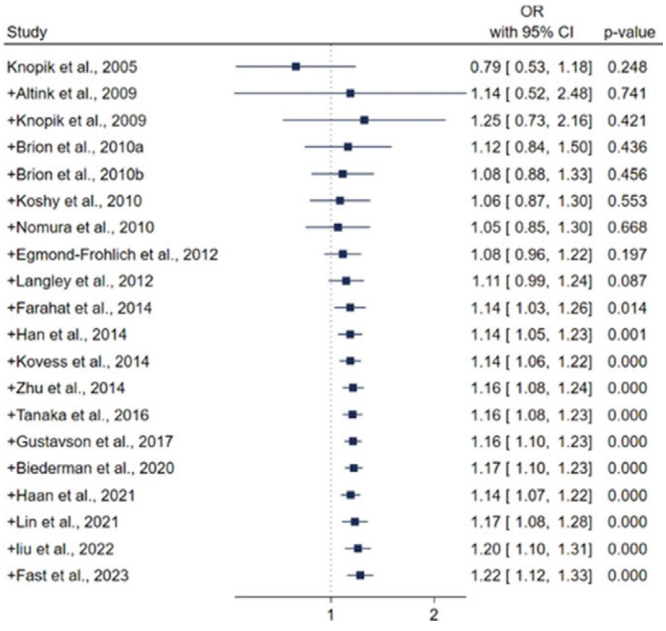
Paternal Smoking and Risk of Attention Deficit Hyperactivity Disorder in Children: A Systematic Review and Meta-Analysis

B. Dachew[1]*, Y. Damtie[1], G. Ayano[1] and R. Alati[1,2]

[1]School of Population Health, Curtin University, Perth and [2]Institute for Social Sciences Research, The University of Queensland, Brisbane, Australia

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.372



Introduction: Attention Deficit Hyperactivity Disorder (ADHD) is a prevalent neurodevelopmental disorder that significantly affects children's behaviour, attention, and academic performance. While the impact of maternal smoking during pregnancy on ADHD risk is well-established, emerging research suggests that paternal smoking may also contribute to this risk. However, the relationship between paternal tobacco use and ADHD remains underexplored, with existing studies presenting mixed results.

Objectives: This systematic review and meta-analysis aim to clarify the extent of this association and provide a comprehensive assessment of the evidence available.

Methods: All relevant studies in CINAHL, Embase, PsycINFO, PubMed, Scopus, and Web of Science databases were searched from inception until 15 March 2024. Both conventional and cumulative meta-analyses were conducted. Pooled odds ratios with 95% confidence intervals (CIs) were calculated using a random-effects model. The heterogeneity among studies was assessed using the I^2 test, and the presence of small study effects was evaluated using funnel plots and Egger's test. Sensitivity and subgroup analyses were also performed.

Results: Twenty observational studies involving over 294, 236 study participants from 16 different countries were included. We found that paternal smoking was associated with a 22% increased risk of ADHD in children (RR=1.22, 95% CI: 1.12, 1.33). The observed association has remained stable since 2014, with minimal fluctuations in effect sizes and their corresponding 95% CIs. Our subgroup analysis revealed that this association is only evident among studies that did not account for maternal smoking (OR=1.23, 95% CI: 1.10, 1.38, *n*=8), while no increased risk of ADHD was found in studies that adjusted for maternal smoking (OR=1.14, 95% CI: 0.98, 1.33), suggesting that maternal smoking may confound the observed association.

Image 1:

Conclusions: Paternal smoking may increase the risk of ADHD in children. Future studies should focus on maternal and paternal

comparisons to disentangle the independent and combined effects of parental smoking on ADHD risk in children.

Disclosure of Interest: None Declared

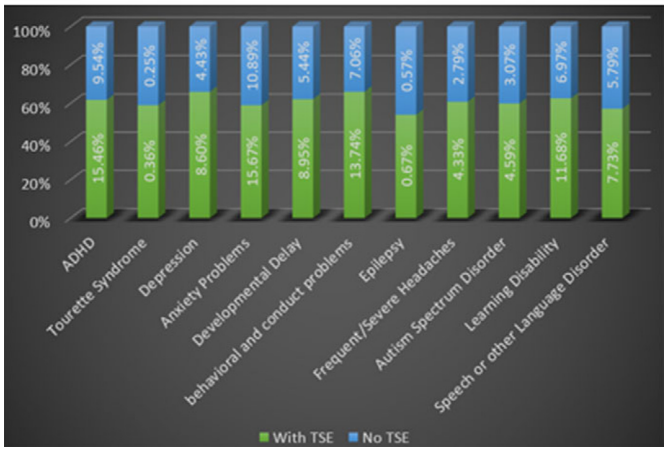
Tobacco Smoke Exposure in Children and Adolescents: Prevalence, Risk Factors and Co-Morbid Neuropsychiatric Conditions in a US Nationwide Study



M. Salehi[1], M. Saeidi[2], N. Kasulis[2], T. Barias[2], T. Kainth[2] and S. Gunturu[2,3]*

[1]Department of Psychiatry, University of Minnesota School of Medicine, Minneapolis; [2]Department of Psychiatry, Bronx Care Health System and [3]Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.373

Introduction: Tobacco smoke exposure(TSE) is a significant public health issue, children and adolescents, who are often involuntarily exposed through secondhand or thirdhand smoke.This exposure has been linked to a range of neuropsychiatric conditions and can negatively impact mental and physical well-being. In the U.S., TSE is prevalent among certain sociodemographic groups, including those with lower income and specific racial backgrounds. The goal of this study was to evaluate the prevalence of TSE and its association with neuropsychiatric comorbidities.
Objectives: Assess TSE prevalence among U.S. children and adolescents
Examine sociodemographic factors influencing TSE
Analyze the link between TSE and neuropsychiatric conditions' prevalence and severity
Methods: This cross-sectional study used data from the 2020-2021 National Survey of Children's Health (NSCH), a survey conducted by the U.S. Census Bureau.Parent-proxy responses were collected in English and Spanish through mail and web-based surveys.A total of 91,404 children aged 0-17 were included for the analysis of TSE prevalence, while 79,182 children aged 3-17 were analyzed for neuropsychiatric comorbidities.The primary measures were TSE, assessed through household smoking behavior, and the presence of neuropsychiatric conditions. Statistical analyses included t-tests, Chi-Square tests, and multivariate regression models to identify associations between TSE, socio-demographic factors, and neuropsychiatric comorbidities, providing adjusted odds ratios and confidence intervals. Statistical analyses were carried out using Stata version 17.
Results: TSE was identified in 12.9% of the sample population. The likelihood of TSE was higher among males and adolescents aged 11-17 years. Children from lower-income households and American Indian/Alaska Native backgrounds had a greater risk of TSE. Among children exposed to tobacco smoke, 36.4% had at least one neuropsychiatric comorbidity, with anxiety (15.7%), ADHD (15.5%), and conduct problems (13.7%) being the most common. Females had lower odds of anxiety and autism spectrum disorder(ASD)compared to males, and Asian children exhibited lower odds of ADHD and other conditions. TSE was associated with increased severity of neuropsychiatric conditions. Figure 1.

Image 1:

Figure 1. Prevalence of co-morbid conditions with and without TSE

Conclusions: TSE is a significant concern among U.S. children and adolescents, particularly affecting males and those from lower-income families. Exposure to tobacco smoke notably elevates the risk and severity of neuropsychiatric conditions, with ADHD, behavioral and conduct problems, and learning disabilities being the most common co-occurring issues. These findings highlight the importance of early screening and intervention for youth exposed to tobacco smoke. Addressing sociodemographic disparities in exposure and implementing prevention strategies could play a critical role in reducing these negative health outcomes.

Time trends in incidence, comorbidities and socio-demographic risk factors for diagnosed autism spectrum disorder among children and adolescents in Finland

Z. Kafami[1,2]*, S. Upadhyaya[1,2], T. Ståhlberg[1,2] and A. Sourander[1,2]

[1]Research center for child psychiatry and [2]INVEST Research Flagship Center, Turku University, Turku, Finland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.374

Introduction: ASD is a neurodevelopmental disorder with 1% prevalence among children and adolescents, with high comorbidity with Intellectual Disability. ASD imposes a significant disease burden and is a leading cause of disability among children and adolescents. Its aetiology is multifactorial, including both genetic and environmental factors. Although prior studies have explored the incidence, comorbidities and several prenatal risk factors, research especifically focusing on ASD categorization by ID is limited.

Objectives: The aim of this study was to report the incidence and cumulative incidence of overall ASD, and HF and LF-ASD categorization, utilizing several national registers.
Methods: This study consisted of all singltone born in Finland between 1998 and 2015 (N=1,044,102), who were diagnosed with ASD from age 3 to 20. We devided study sample into four cohorts by birth year: 1998-2002, 2003-2007, 2008-2011 and 2012-2015. We also categorized ASD into LF-ASD and HF-ASD, based on their comorbidity with ID (ICD 10 codes: F70-F79). All cases (n=10,171) were matched with Controls (n=49,391) on the age, gender and place of birth. We limited our study of other psychiatric disorders comorbidities to the oldest birth cohort, born in 1998-2002. The association between sociodemographic risk factors and ASD cases and separately for HF-ASD and LF-ASD was analysed using Conditional logistic regression.
Results: The incidence of ASD increased with age, specifically among girls. Among the birth cohorts, the cumulative incidence of HF-ASD increased from 0.52 (95% CI 0.49-0.54) to 0.89 (95% CI 0.84- 0.94), by age 10, while in the cumulative incidence of LF-ASD remained stable at 0.17 (95% CI 0.16-0.19). Several sociodemographic risk factors were associated with both HF-ASD and LF-ASD, except for parental immigration, which was only associated with LF-ASD. A total of 58.99% cases had at least one comorbid diagnosis, 35.91% of HF-ASD and 31.86% of LF-ASD. The most common comorbid diagnoses among HF-ASD cases were ADHD (33.9%), depressive disorder (25.4%) and anxiety disorder (23.9%). Among LF-ASD cases were ADHD (17.2%), anxiety disorder (10.5%) and Schizophrenia (5.2%).
Conclusions: The incidence of diagnosed ASD increased with age from 1998-2018, especifically HF-ASD. This result could indicate a real increase in incidence or is due to improved access to mental health services and enhanced awareness of ASD among population and professionals. The rise in ASD incidence underscores the need for specialized mental health services and social support. The association between immigration and the risk of ASD highlights the importance of ensuring mental health services are accessible to immigrants.

Sleep impairment as a therapeutic target to treat opioid use disorder

L. Li

Psychiatry, University of Alabama at Birmingham, Birmingham, United States
doi: 10.1192/j.eurpsy.2025.375

Introduction: Opioid use disorder (OUD) is a national public health concern. Craving is a diagnostic criterion and is also implicated in the risk of relapse to opioids. Although sleep impairment is believed to relate with OUD, little research to date has examined the relationship between sleep components and craving in individuals with OUD as well as the moderators in the relationship.
Objectives: This cross-sectional study was designed to address the relationship between sleep disturbance and OUD.
Methods: Individuals with current OUD (n=51) were enrolled. Each participant completed validated scales, including the Pittsburgh Sleep Quality Index for sleep, and Barratt Impulsiveness Scale for impulsivity, and the Opioid Craving Scale for cravings. Correlation and moderation analyses were performed using SPSS, v29.
Results: Total scores of the PSQI were significantly associated with cravings (r=0.44, p=0.006). Among sleep components, sleep quality, sleep efficiency, and sleep disturbance were significantly associated with cravings, while four other sleep components were not. Impulsivity moderated the relationship between sleep impairment measured using total score of the PSQI and cravings for participants (b=0.15, p<.05).
Conclusions: Although preliminary, the findings add to literature on craving, impulsivity, and sleep among individuals with OUD. Sleep impairment and impulsivity may be important targets of a comprehensive, long-term treatment plan for some patients with OUD.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.377

Introduction: Pathological anxiety in social anxiety disorder (SAD) is characterized by dysregulated arousal and altered cardiac autonomic responses, with lower heart rate variability (HRV) potentially indicating emotional dysregulation.
Objectives: This study aimed to explore the relationship between peripheral and central autonomic nervous system activity during emotional processing in patients with SAD.
Methods: Thirty-two patients with SAD and 41 healthy controls participated in a passive viewing task that alternated between neutral and angry faces. We analyzed correlations between brain activation during emotional processing and root mean square of successive differences (RMSSD) in HRV during both resting state and task conditions.
Results: Unlike the controls, the SAD group showed a trend toward significant correlations between baseline RMSSD and left anterior insula activity during neutral face processing (R^2 = 0.118, β = -0.003, F= *3.886*, p = .058) and significant correlations with both left anterior insula and

© The Author(s), 2025. Published by Cambridge University Press on behalf of European Psychiatric Association.

right amygdala activities during angry face processing (R^2 = 0.157, β = -0.003, F= 5.415, p = .027 and R^2 = 0.135, β = -0.002, F= 4.360, p = .046, respectively). In the control group, task RMSSD was significantly correlated with right amygdala and right dorsomedial prefrontal cortex activities during neutral face processing (R^2 = 0.160, β = -0.003, F=6.284, p = .017 and R^2 = 0.222, β = -0.009, F=9.443, p = .004, respectively), while in the SAD group, correlations were found with the right parahippocampal gyrus (R^2 = 0.148, β = -0.002, F=4.5, p = .044). Additionally, only in the control group, RMSSD during neutral face trials was significantly correlated with neural activation during angry faces processing (R^2 = 0.132, β = -0.002, F=4.856, p = .035).

Conclusions: This study identifies distinct patterns of autonomic and neural responses to emotional stimuli in SAD patients, highlighting heightened autonomic readiness and reduced flexibility when processing social threats.

Effectiveness of the Early Adolescent Skills for Emotions (EASE) Intervention in Alleviating Post-Traumatic Stress Disorder: A Systematic Review and Meta-Analysis of Randomized Controlled Trials

V. Astori[1]*, B. Westphalen Pomianoski[2], D. Lopes Vieira[3], M. Prätzel Ellwanger[4] and M. Frizzo Messinger[5]

[1]Escola Superior de Ciências da Santa Casa de Misericórdia de Vitória, Vitória; [2]Universidade Nove de Julho, São Paulo; [3]Universidade Federal de Minas Gerais, Belo Horizonte; [4]Universidade do Contestado, Mafra and [5]Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.378

Introduction: The Lancet Commission noted severe mental health service disparities in low- and middle-income countries facing crises. Regarding this, the World Health Organization (WHO) developed the early adolescent skills for emotions (EASE), an experimental group-based intervention delivered by non-specialists, to offer evidence-based psychological support for adolescents with mental distress.

Objectives: This systematic review and meta-analysis assesses EASE's effectiveness in alleviating post-traumatic stress disorder (PTSD) compared with enhanced treatment as usual (ETAU).

Methods: We systematically searched PubMed, Cochrane, and Scopus for randomized controlled trials (RCTs) comparing EASE with ETAU. Our outcomes included the overall improvement in post-traumatic and depressive symptoms, measured by the Children's Revised Impact of Event Scale (CRIES-13) and the Patient Health Questionnaire-Adolescent version (PHQ-A) scores respectively. We pooled mean differences (MD) with 95% confidence intervals (CI) in RStudio using a random-effects model. Heterogeneity was assessed with I^2 statistics.

Results: Six RCTs were included with 1,417 patients, of whom 642 (45.3%) received EASE treatment. In 67% of the studies, Syria was the main location of RCT's. A total of 688(49%) were female. CRIES-13 (MD = -0.18, 95% CI [-1.88, 1.52], p = 0.84, I^2 = 0%; Figure 1) and PHQ-A (MD = -0.69, 95% CI [-1.47, 0.09], p = 0.08, I^2 = 15%; Figure 2) scores in the EASE intervention group compared to the ETAU group showed no significant difference. In both outcomes the heterogeneity was low.

Image 1:

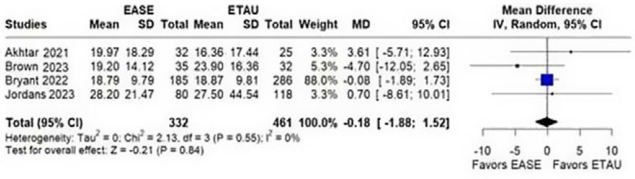

Figure 1 - There was no significant difference between groups in CRIES-13 (P = 0.84) scores.

Image 2:

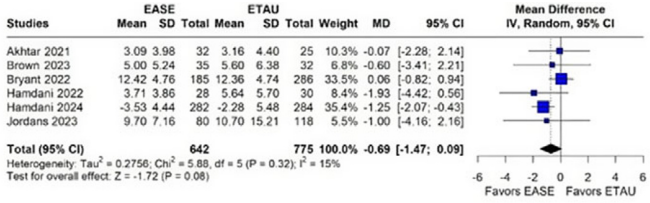

Figure 2 - There was no significant difference between groups in PHQ-A (P = 0.08) scores.

Conclusions: The benefit of EASE in improving mental distress in adolescents is uncertain. Additional trials will provide new evidence for EASE potential therapeutic benefits.

The Moderating Role of Coping Self-efficacy on the Relationship Between Stress and Psychosomatic Symptoms in Adolescents: A Moderation Analysis

M. Klein[1,2]*, D. Várnai[2,3], Á. Németh[2] and G. Kökönyei[2,4,5]

[1]Doctoral School of Psychology; [2]Institute of Psychology, ELTE Eötvös Loránd University; [3]Heim Pal National Institute of Pediatrics; [4]NAP3.0-SE Neuropsychopharmacology Research Group, National Brain Research Program and [5]Department of Pharmacodynamics, Faculty of Pharmacy, Semmelweis University, Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.379

Introduction: Adolescents face significant stress, which can undermine their subjective health, often manifesting as psychosomatic symptoms. Perceived self-efficacy is a critical resource for resilience, potentially buffering the impact of stress on subjective health. While action self-efficacy indicates one's perceived ability to set goals and take initiative, coping self-efficacy refers to one's ability to

achieve the goals. By investigating both components, researchers and mental-health professionals can better understand how different aspects of self-efficacy influence the stress-symptom relationship, providing a more nuanced view of coping mechanisms.
Objectives: The aim of this study is to determine how these key components of self-efficacy - action self-efficacy and coping self-efficacy - moderate the relationship between stress and psychosomatic symptoms.
Methods: The analyses were based on the Hungarian contribution to the representative international Health Behaviour in School-aged Children (HBSC) survey, collected in 2021/2022. The study population comprised self-report data from high-school students (N = 3,410; mean age = 16.77 years). We examined the main effects of self-efficacy dimensions and perceived stress, and their interactions in explaining psychosomatic complaints, using linear regression analysis with Hayes' PROCESS macro (Model 1) in SPSS. Age and gender were controlled for as covariates.
Results: *Coping self-efficacy*: The overall model explained 33% of the variance in psychosomatic symptoms ($R^2 = 0.33$, $F(5, 3404) = 330.96$, $p < .001$). The results showed that stress ($b = 1.93$, $p < .001$), coping self-efficacy ($b = 2.18$, $p = .02$), and their interaction ($b = -0.33$, $p = .002$) were significant explanatory variables. This suggests that the relationship between stress and psychosomatic symptoms is weaker among adolescents who reported stronger coping self-efficacy. *Action self-efficacy*: In contrast, the interaction between stress and action self-efficacy was not significant ($p = .16$), implicating that the ability to set goals did not mitigate the effect of stress on symptoms.
Conclusions: The findings imply that coping self-efficacy significantly reduces the relationship between stress and psychosomatic symptoms. Adolescents with stronger coping skills are better equipped to mitigate the adverse effects of stress. However, action self-efficacy did not show a significant moderating effect, highlighting the distinct roles different self-efficacy components play in stress management. These results emphasize the importance of enhancing coping skills, such as cognitive reappraisal, in primary prevention interventions to reduce stress-induced psychosomatic symptoms.

Effects of Additional Yoga Intervention in Children and Adolescents with Major Depressive Disorder: A Randomized Controlled Trial

B. N. Patra[1]*, R. Sagar[1] and G. Sharma[2]
[1]Psychiatry and [2]Cardiology, AIIMS, NEW DELHI, New Delhi, India
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.380

Introduction: Depression is one of the most common mental health disorders in children and adolescents. In India, many parents resist psychotropic medication for children due to potential side effects, highlighting the need for non-pharmacological interventions like yoga.
Objectives: The current study investigates the impact of additional yoga therapy on depressive symptoms, global functioning, and parental stress among children and adolescents diagnosed with Major Depressive Disorder (MDD) on children seeking treatment at the Department of Psychiatry of a tertiary care medical institute in India.
Methods: This study included 80 participants aged 6 to 17 years. After taking written informed consent from the parents and assents from the adolescents, they were randomized into two groups: one receiving yoga Therapy alongside treatment as usual (TAU) and the other a waitlist control group receiving only TAU. Assessments were done on both children and their parents, and the instruments included were Centre for Epidemiological Studies Depression Scale for Children (CES-DC), the Children's Global Assessment Scale (CGAS), the Clinical Global Impression scale (CGI), and the Depression Anxiety and Stress Scale (DASS) for parents. Follow-up assessments occurred at 6 and 12 weeks.
Results: In the experimental group, CES-DC scores showed significant improvements, with p value < 0.01 at 6 weeks and < 0.01 at 12 weeks. Global functioning scores also improved, recording p values of < 0.01 at 6 weeks and < 0.01 at 12 weeks. The control group also exhibited results, with CES-DC p values of < 0.01 at 6 weeks and < 0.01 at 12 weeks. Global functioning scores revealed p values of < 0.01 at 6 weeks and < 0.01 at 12 weeks. However, there were no significant differences in the improvement in CES-DC score and functioning in the experimental and control group at the end of 6 weeks and 12 weeks. At the baseline, at end of 6 weeks and at the end of 12 weeks, there were no significant differences in parental depression, anxiety, and stress score.
Conclusions: Yoga therapy was beneficial for the children and adolescents with major depressive disorder. However, there were no significant differences in the improvement in depression and functioning in the experimental and control group.

The BDNF/proBDNF ratio as a predictor of antidepressant treatment response in adolescent girls

W. Zwolińska[1,2]*, K. Bilska[3], N. Pytlińska[1], M. Skibińska[3], M. Dmitrzak-Węglarz[3] and A. Słopień[1]
[1]Child and Adolescent Psychiatry Clinic; [2]Doctoral School and [3]Department of Psychiatric Genetics, Poznan University of Medical Sciences, Poznan, Poland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.381

Introduction: The role of the brain-derived neurotrophic factor (BDNF) in the pathophysiology of depression is well established,

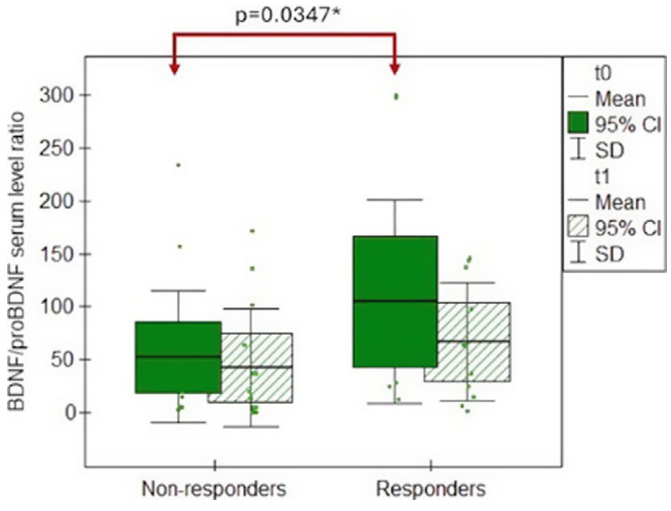
with decreased BDNF levels being associated with the emergence of depressive symptoms. More recent studies have reported that the precursor protein – proBDNF – might also be involved in the pathogenesis of depression since both particles are biologically active and elicit opposing effects: mature BDNF promotes the proliferation of neurons and synaptogenesis, while proBDNF evokes neuronal death. The BDNF/proBDNF ratio has been suggested as a possible biomarker of depression state and treatment response among adults with depression. However, no study has analyzed BDNF/proBDNF serum ratio levels in adolescent depressed patients.

Objectives: We aimed to verify the changes in serum BDNF/proBDNF ratio levels during the course of treatment in adolescents with depression in relation to healthy control. We also aimed to investigate whether this parameter could predict the antidepressant treatment outcome.

Methods: Thirty female inpatients, aged 11-17, diagnosed with a first-lifetime depressive episode were assessed at two time-points: before (t0) and after (t1) the minimum six-week period of the first-line antidepressant treatment and compared with thirty age-matched healthy girls. The assessment at t0 and t1 involved the analysis of BDNF and proBDNF serum levels (ELISA method) and clinical symptoms evaluation using standardized depressive symptoms scales: Children's Depression Inventory (CDI-2) and Hamilton Depression Rating Scale (HDRS). Patients with at least 50% symptom reduction in CDI-2 and HDRS or HDRS<7 were classified as 'responders.' The control group underwent one-time BDNF and proBDNF evaluation. The BDNF/proBDNF ratio has been calculated.

Results: The BDNF/proBDNF serum ratio did not significantly differ between the studied and control groups. We proved no significant differences in BDNF/proBDNF serum ratio before and after the antidepressant treatment, regardless of the treatment outcome. However, responders had a significantly higher pretreatment BDNF/proBDNF ratio when compared with non-responders (Figure 1). The ROC analysis revealed that the BDNF/proBDNF ratio at t0 could predict the remission status at t1 with a sensitivity of 66.67% and a specificity of 81.25% (Figure 2).

Image 1:



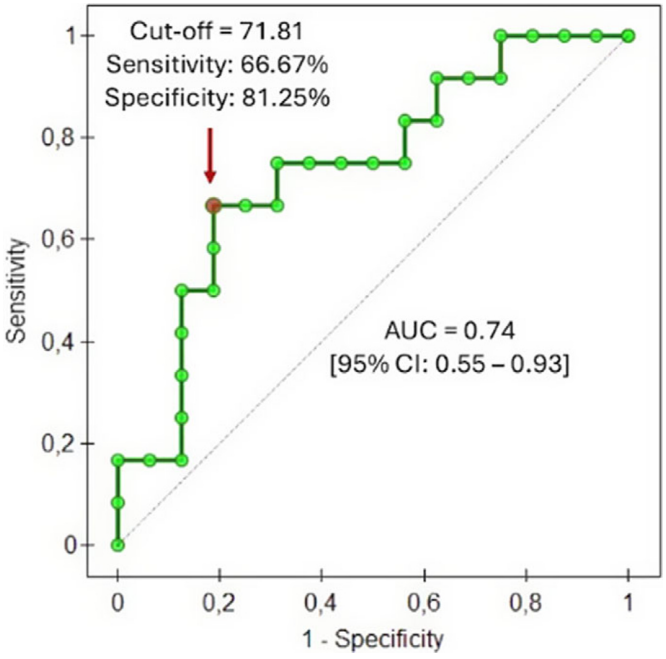


Image 2:

Conclusions: Pretreatment BDNF/proBDNF ratio could be considered a possible biomarker predictive of antidepressant treatment response in adolescent girls.

Genetic overlap of severe psychiatric disorders with lung function and asthma suggests shared biological mechanisms

Z. Lu[1]*, A. Ploner[1], P. Jaholkowski[2], A. Shadrin[2], B. Brew[1], O. Andreassen[2] and S. Bergen[1]

[1]Karolinska Institutet, Stockholm, Sweden and [2]Oslo University, Oslo, Norway

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.382

Introduction: Severe psychiatric disorders, including schizophrenia (SCZ), bipolar disorder (BIP) and anorexia nervosa (AN), are frequently comorbid with lung function decline and asthma. Despite considerable heritability, the genetic relationships between severe psychiatric and respiratory comorbidities are inconclusive.

Objectives: We aimed to thoroughly investigate the shared genetic architecture between three severe psychiatric disorders (SCZ, BIP and AN) and lung function (forced expiratory volume/forced vital capacity ratio) or doctor-diagnosed asthma based on available genome-wide association studies.

Methods: We performed linkage disequilibrium score regression analyses (LDSC) and MiXeR to quantify the genetic overlap. A conditional/conjunctional false discovery rate (cond/conjFDR) approach was employed to detect shared genomic loci. Functional annotations, gene mapping and gene-based enrichment analyses were adopted to explore shared biological mechanisms. Web-based cell-type-specific enrichment analysis (WebCSEA) was employed to identify the cell types enriched for shared genes across tissues. Transcriptome analyses were conducted via S-PrediXcan to prioritize biologically plausible shared genes in relevant tissues.
Results: Despite weak or null genetic correlations identified by LDSC, MiXeR analyses demonstrated extensive moderate polygenic overlap (~400 to 800 shared variants) across all pairs of psychiatric and respiratory phenotypes. The cond/conjFDR approach detected a total of 378 unique loci jointly associated with severe psychiatric disorders and lung function or asthma, harboring a mix of concordant and antagonistic variants. Gene-based enrichment analyses applied to the 4,105 genes mapped to shared loci highlighted cell types including type II pneumocytes and macrophages in lung and monocytes in blood as well as biological processes involving the interferon (IFN) JAK-STAT pathway and natural killer cell activation, suggesting common immune mechanisms. Furthermore, when stratified by respiratory outcome, genes shared with asthma were enriched for immunity-related pathways, whereas genes shared with lung were enriched for non-immune mechanisms, indicating divergent shared etiology. A total of 22 shared genes identified by conjFDR approach were prioritized as biologically plausible in transcriptome analyses.
Conclusions: This study reveals the complicated shared genetic etiology between severe psychiatric disorders and lung function or asthma and implicates overlapping immune and non-immune mechanisms. Our findings suggest that individuals with severe psychiatric disorders should be screened for lung function decline and asthma in clinical settings.

AI-based diagnosis of depression and cardiovascular disease comorbidity based on big data

V. Pezoulas[1], K. Dobretz[2], G. Ehret[2], D. Fotiadis[1] and A. Sakellarios[3]*

[1]Dept. of Materials Science and Engineering, University of Ioannina, Ioannina, Greece; [2]Department of Internal Medicine Hôpitaux, Universitaires de Genève, Genève, Switzerland and [3]Dept. of Mechanical and Aeronautics Engineering, University of Patras, Patras, Greece
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.383

Introduction: There is strong clinical evidence that patients with depression have high probabilities to present a cardiovascular disease and vice versa. Thus, it is important to accurately identify these patients in order to provide the optimal management of the comorbid conditions.
Objectives: To identify patients who have depression and cardiovascular disease using social and molecular biomarkers which are routinely collected in the clinical practice.
Methods: Data from 502,379 participants in the UK Biobank were utilized in this work. A subset of the participants has a mental assessment using questionnaires about the presence of depression. CVD assessment was also available for the majority of the patients. In total, 126,033 participants had clinical assessment of both depression and CVD. From these, 8,925 patients had both comorbid conditions. An automated medical data curation tool described in a previous study was utilized to detect and mitigate data inconsistencies and elevate the input data integrity and usability. Hybrid boosting ensembles, including the XGBoost algorithm with a customized hybrid loss function was trained on the curated data, to reduce training and testing loss and to avoid overfitting effects. Dropout rates from deep learning theory were used in the hybrid loss function to further reduce biases during the decision-making process by controlling for the shape of the loss function. Random downsampling with replacement was also applied to match the control and target populations due to the increased class imbalance (ratio?) and with respect to the pre-defined set of confound factors. Additional classifiers including bagging classifiers were used for comparison purposes. The classification performance was assessed based on stratified 10-fold cross validation, where various metrics like the accuracy, sensitivity, specificity and area under the ROC curve scores were estimated. Advanced feature selection methods from coalition game theory, including the Shapley additive explanation (SHAP) exploratory analysis was utilized to identify predictors with positive or negative impact to have both the comorbid conditions These explanations were based on the classification outcomes from specific training and testing instances.
Results: The XGBoost classifier had the best performance among all tested classifiers. The results were 0.85, 0.88, 0.81 and 0.92 for the accuracy, sensitivity, specificity and AUC, respectively. The figure 1, presents the explainability analysis for the selected biomarkers. As shown, there are simple social questions, but also some blood biomarkers which can be used for the identification of the patients with both the comorbid conditions of depression and CVD.

Image 1:

Conclusions: We developed an AI-based approach which can diagnose depression and CVD to patients in a cost effective way with accuracy of 85% and AUC equal to 0.92.

Relationship between BMI and affective disorders: results from a multicenter observational study

C. Toni[1]*, B. Della Rocca[1], M. De Vincenzo[1], E. Mancuso[1], V. Dello Stritto[1], V. Coppola[1], G. Sampogna[1], M. Luciano[1] and A. Fiorillo

Psychiatry, University of Campania "Luigi Vanvitelli", Naples, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.384

Introduction: Patients suffering from severe mental disorders have a reduced life expectancy of approximately 10-25 years compared to the general population. This mortality gap is mainly due to physical comorbidities among which metabolic disorders play a significant role.
Objectives: In our study we used the Body Mass Index (BMI), an indicator of general health that can be easily calculated in daily clinical practice, to investigate how weight and the different psychopathological and psychosocial dimensions mutually influence each other in patients with mental disorders.
Methods: This naturalistic observational multicenter study was carried-out in 7 Italian university centers (Universities of Campania "L. Vanvitelli," Catania, Magna Graecia of Catanzaro, Cattolica del Sacro Cuore of Rome, Padova, Sapienza University of Rome, and Tor Vergata of Rome). Patients were recruited if they: 1) had diagnosis of bipolar disorder (BD) or major depressive disorder (MDD) according to DSM-5 criteria; 2) had an age between 18 and 65 years; 4) were in a stable phase of the disease (total score < 9 on the Hamilton Rating Scale for Depression and a score of ≤11 on the Young Mania Rating Scale). Affective temperaments were assessed with the Munster Temperament Evaluation of the Memphis, Pisa, Paris, and San Diego, impulsivity with the Barratt Impulsiveness Scale, and suicidal ideation with the Columbia Suicide Severity Rating Scale.
Results: A total of 598 patients were recruited, of which 60.9% affected by DB and 39.1% by MDD. Univariate analyzes revealed an association between higher BMI and male gender ($p<0.001$), BD diagnosis ($p<0.001$), high levels of impulsivity ($p<0.05$), presence of psychotic symptoms during the acute phases of illness ($p<0.05$), greater number of hospitalizations ($p<0.01$), cigarette smoking ($p<0.05$) and depressive temperament ($p<0.001$). Furthermore, patients treated with lithium ($p<0.05$), antiepileptics ($p<0.05$) and first-generation antipsychotics ($p<0.001$) had a significantly higher BMI compared to those not taking the aforementioned pharmacological treatments.
Conclusions: The results of our study highlight a strong link between BMI and some clinical outcomes in patients with affective disorders. The routinary assessment of these outcomes would be useful for the early identification of potential metabolic comorbidities as well as to identify patients at higher risk to develop a worse outcome.

Predictors of Presence of and Search for Meaning in Life among Omani Students during the COVID-19 Pandemic: A Cross-sectional Study

T. Al-Mahrouqi[1]*, R. Al-Obeidani[2], M. Elsherif[3], M. Al Shehi[1], M. Al-Mukhaini[4], S. Al-Huseini[1], F. Jahan[4], N. Al Balushi[2] and M. Al-Alawi[2]

[1]Oman Medical Speciality Board; [2]Sultan Qaboos University Hospital, Muscat, Oman; [3]Ministry of Health, Kuwait, Kuwait and [4]National University of Science and Technology, Muscat, Oman
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.385

Introduction: While various fields and work areas have been impacted due to COVID-19, undergraduate students appear to have compounded stress. We sought to investigate the variables that predict meaning in life for Omani college students during the COVID-19 pandemic.
Objectives: This study investigated the personal and academic factors associated with the presence and search for meaning in life among college students in Oman.
Methods: A cross-sectional study was conducted in April 2021. A self-reported survey comprising the Meaning in Life Questionnaire (MLQ) and a sociodemographic questionnaire was completed by 970 students at the National University of Science and Technology in Oman. We used multiple linear regression to explore the independent predictors.
Results: Compared with engineering students, medical students were found to have a higher degree of both the presence of meaning in life as well as the search for meaning in life (p-value 0.001), and with each advancing academic year, the presence of meaning in life was found to be lower (p-value = 0.002). Students with chronic physical disease had a lower degree of presence of meaning in life and a lower degree of search for meaning in life ($p = 0.001$) compared with those without chronic disease. In addition, mental illness was associated with a lower degree of presence of meaning in life (p-value 0.001) and financial strain was associated with a lower degree of presence of meaning in life (p-value = 0.001).
Conclusions: In conclusion, no prior research demonstrated higher levels of meaning in life among medicine major students compared to those in engineering or pharmacy majors. Moreover, other academic, socio-economic, and health-related factors correlated with individuals' sense of meaning & search in life. Therefore, psychologists and psychiatrists should consider these diverse factors when designing interventions to support individuals in exploring and enhancing their meaning in life, considering their unique needs and contexts.

Adapting the Thinking Healthy Programme for Perinatal Depression: A Culturally Tailored Approach in Three Central African Countries

E. Dozio[1]*, V. Wamba[2] and I. PUEUGUEU[3]

[1]Action contre la Faim, Paris, France; [2]Action contre la Faim, Goma, Congo, The Democratic Republic of the and [3]Action contre la Faim, Bangui, Central African Republic
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.386

Introduction: In humanitarian settings, populations face extreme adversity, and women in the perinatal period are particularly vulnerable, often at heightened risk of depression. This impacts not only their mental health but also their ability to care for themselves and their newborns, presenting a serious challenge for maternal and infant well-being.
Objectives: This project aimed to reduce the risk of perinatal depression while strengthening infant care practices and parenting skills, ensuring that mothers, despite living in distressing and hostile environments, can be in the best possible state of mind to care for their babies.
Methods: As part of Action contre la Faim's psychosocial support projects, we adapted the WHO's "Thinking Healthy" (TH) protocol specifically for low- and middle-income countries (LAMIC), focusing on cultural sensitivity and the unique challenges of the intervention areas. The standard manual was condensed into three sessions, with additional cultural adaptations and the inclusion of two projective sessions (protolanguage approach) to allow women more freedom to express their specific challenges. The protocol was delivered to groups of up to eight women, separated based on whether they were pregnant or breastfeeding to better target their unique needs. Due to logistical and security constraints, the TH protocol required further adaptation to fit each context's specific limitations.
Results: Over the past three years, the adapted TH protocol has been implemented in three countries across Central Africa, including both humanitarian crisis zones and more stable developmental settings. The programme reached approximately 5,000 preganant women, mothers, and their babies. It was delivered not only in healthcare centres but also directly in communities and internally displaced person (IDP) camps, providing wider access. Results demonstrated significant reductions in psychological distress and depressive symptoms, with improved mother-infant interactions. The programme also helped train healthcare workers, including midwives, enhancing local capacity for long-term support. Quantitative and qualitative results, along with details of cultural adaptations, will be presented.
Conclusions: The adaptation of the Thinking Healthy protocol for low-resource, high-stress environments proved to be an effective and scalable approach for addressing perinatal depression. By tailoring the intervention to fit the cultural and logistical realities of Central Africa, we were able to provide meaningful support to thousands of families. The programme not only reduced depressive symptoms but also fostered stronger maternal-infant bonds and built local healthcare capacity. This model can serve as a reference for implementing mental health interventions in similar contexts globally.

EPP023

Implementing a peer-led psychological self-support program in resource-limited contexts: a pilot in Eastern Cameroon

E. Dozio

Action contre la Faim, Paris, France
doi: 10.1192/j.eurpsy.2025.387

Introduction: In Eastern Cameroon, the psychological needs of both Central African refugees and host communities are significant. Following psychological group interventions over a two-month period, many participants expressed a desire to continue the support process. To meet this need, a self-support protocol was implemented to encourage participants to maintain and strengthen their emotional and social bonds.
Objectives: The aim of this intervention was to enable participants to continue engaging in psychological support autonomously, enhancing their well-being, resilience, and coping mechanisms. The program sought to provide tools for ongoing emotional regulation and peer support, addressing the psychosocial challenges identified during the initial psychological care.
Methods: A flexible, peer-led protocol was developed and implemented after group psychological sessions. Participants were invited to form their own self-support groups, with a recommended size of up to 10 members, meeting weekly for approximately 90 minutes. The structure was intentionally loose to promote autonomy, creativity, and peer leadership. Two initial sessions were facilitated by psychosocial supervisors, while subsequent meetings were primarily observed to assess group evolution. Key dimensions such as emotional well-being, resilience, and social cohesion were measured pre- and post-intervention.
Results: The qualitaive analysis revealed increased cohesion and social connection between group members, especially between refugees and host communities. Participants reported feeling empowered and valued the emotional stability gained through the exercises introduced during the program. However, the evaluation also highlighted challenges, such as maintaining motivation without ongoing supervision and the need for economic opportunities to sustain long-term engagement.
Conclusions: This self-support protocol demonstrated the feasibility and positive impact of peer-led psychological care in contexts with limited resources. The program reinforced emotional resilience, social cohesion, and mutual support, but future iterations should consider integrating economic empowerment initiatives and more structured follow-up to ensure sustained participation.

Challenges and Solutions for Psychiatry's Approach to Indigenous People

L. Mehl-Madrona[1,2]* and B. Mainguy[3]

[1]Native Studies, University of Maine, Orono; [2]Psychiatry Residency, Northern Light Acadia and [3]Wabanaki Health and Wellness, Bangor, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.388

Introduction: Psychiatry has historically underserved Indigenous people. Earlier, cross-cultural psychiatry assumed that psychiatric disorders were universal and varied little across cultures. This approach has not worked well for Indigenous people who may have different views of mind and mental health. For example, Indigenous philosophy tend to explain the world and states of mental health from a storied approach encompassing relations to land, spiritual beings, ancestors, and the community which can result in different conclusions from conventional psychiatry.
Objectives: We wanted to explore what modifications in their approach practicing psychiatrists have made to be successful in Indigenous communities and to determine what was common among how communities in which they worked conceptualized mind and mental health.
Methods: We interviewed psychiatrists working in Indigenous communities regarding what was effective and how they had changed their practice to work in those communities and how those communities had changed them. We used the iterative processing of constructivist grounded theory to find commonalities in their responses. We present from rural and remote Indigenous settings in Canada (Saskatchewan and Northern Ontario), New Zealand, and Maine (USA).
Results: We found a modified approach to psychiatric services that emphasized Indigenous values and that determined positive aspects of the client's history as well as problem areas and engaged the client in therapy from the beginning of the evaluation. Some key concepts that emerged from qualitative analysis of interviews and case histories using constructivist grounded theory as a method of analysis included (1) reframing the person's self-story within a threat-power-meaning network, (2) working with stories about the spirit of the suffering, (3) exploring right relationships and meaningful conduct, (4)acknowledging the intergenerational transmission of suffering. Physicians came to understand that the client sets their goals and defines what recovery means for them in discussion with their family and important community members including elders. This led to a different understanding of what privacy meant to clients. Indigenous cultures encountered were different but appeared to share some similarities including a highly relational approach to defining the self, a collectivist mindset in which the needs of the group can supersede the needs of the individual, a reliance upon stories for transmission of knowledge and culture, and a commitment to a biopsychosocial and spiritual approach.
Conclusions: Psychiatry can form effective collaborative relationships with Indigenous communities requring modifications in the usual worldview and orientation to how psychiatry is practiced.

Burnout among teachers in three Canadian Provinces: Findings from the Wellness4Teachers Support Program

A. Belinda[1]*, R. D. L. Dias[2], Y. Wei[1] and V. I. O. Agyapong[1,2]
[1]University of Alberta, Edmonton and [2]Dalhousie University, Halifax, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.389

Introduction: Burnout is a longstanding issue among educators and has been associated with psychological and physical health problems such as depression, and insomnia.Chronic stress has been associated with burnout, defined by three dimensions of overpowering exhaustion (emotional exhaustion), cynicism (feelings of cynicism and detachment from work), and inefficacy (a sense of ineffectiveness and lack of accomplishment) which conceptualize the individual stressful experience in a social context.
Objectives: To assess the prevalence and predictors of the three dimensions of burnout (emotional exhaustion, depersonalization and lack of professional accomplishment) among elementary and high school teachers.
Methods: This is a quantitative cross-sectional study with data collected via an online survey. The Maslach Burnout Inventory-Educator Survey (MBI-ES), the Brief Resilience Scale (BRS) and the Perceived Stress Scale were used, respectively, to assess burnout, resilience and stress among teachers. Data was collected between September 1st, 2022 and August 30th, 2023. SPSS (version 28, IBM Corp) was used for the data analysis.
Results: Overall, 1912 educators received a link to the online survey via a text message, and 780 completed the burnout survey questions, resulting in a response rate of 41%. The prevalence of emotional exhaustion, depersonalization, and lack of professional accomplishment were 76.9%, 23.2%, and 30.8%, respectively. Participants with high-stress symptoms were 6.88 times more likely to experience emotional exhaustion (OR = 6.88; 95% CI: 3.31–14.29), 2.55 times (OR = 2.55; 95% CI: 1.65–3.93) more likely to experience depersonalization and 2.34 times (OR = 2.34; 95% CI: 1.64–3.35) more likely to experience lack of professional fulfilment. Additionally, respondents with low resilience were 3.26 times more likely to experience emotional exhaustion symptoms (OR = 3.26; 95% CI: 2.00–5.31),) than those with high resilience. Males were about 2.4 times more likely to present with depersonalization compared to female teachers, whilst those who indicated their marital status as partnered or cohabiting and those who selected "other" were 3.5 and 7.3 times respectively more likely to present with depersonalization compared with those who were single. Finally, Physical Education were 3.8 times more likely to present with depersonalization compared with English teachers.
Conclusions: The current study highlights the predictive effects of low resilience and high stress on the three dimensions of burnout among teachers in Canada. Interventions aimed at addressing systemic stress and fostering resilience are needed to reduce burnout among teachers.

doi: 10.1192/j.eurpsy.2025.390

Introduction: Many people experience at least one traumatic event in their lifetime. Although such traumatic events can precipitate psychiatric disorders, many individuals exhibit high resilience by adapting to such events with little disruption or may recover their baseline level of functioning after a transient symptomatic period.
Objectives: To investigate the prevalence and correlates of low resilience in patients before discharge from psychiatric acute care facilities.
Methods: Respondents for this study were recruited from nine psychiatric in-patient units across Alberta. Demographic and clinical information were collected via a REDCap online survey. The brief resilience scale (BRS) was used to measure low resilience. A chi-square analysis followed by a binary logistic regression model was employed to identify significant predictors of low resilience.
Results: Overall, 1004 participants took part in this study; 360 (35.9%) were less than 25 years old, 269 (34.7%) were above 40 years old, and most participants were females 550 (54.8%) and Caucasians 625 (62.3%). The prevalence of low resilience in this cohort was (555/1004, 55.3%). Respondents who identified as female were one and a half times more likely to show low resilience (OR=1.564; 95% C.I.=1.79-2.10), while individuals with 'other gender' identity were three and a half times more likely to evidence low resilience (OR=3.646; 95% C.I.=1.36-9.71) compared to male gender persons. Similarly, Caucasians were two and one-and-a-half times respectively more likely to present with low resilience compared with respondents who identified as Black people (OR=2.21; 95% C.I.=1.45-3.70) and Asians (OR=1.589; 95% C.I.=1.45-2.44). Additionally, persons with a diagnosis of depression were more than two times and four times, respectively, more likely to present with low resilience than those with bipolar disorder (OR=2.567; 95% C.I.=1.72-3.85) and those with schizophrenia (OR=4.081;95% C.I.= 2.63-6.25)
Conclusions: Several demographic and clinical factors were identified as predictors of likely low resilience. The findings may facilitate the identification of vulnerable groups to enable their increased access to support programs that may enhance resilience.

The Integration of AI-Driven Wearable Technology in Psychiatry: Advancing Early Detection and Personalized Management of Psychiatric Disorders

M. Peyioti[1]*, P. Argitis[2], A. Karampas[3], M. Demetriou[2], V. Anagnostopoulou[2] and Z. Chaviaras[2]

[1]University General Hospital of Alexandroupolis, Alexandroupolis; [2]Psychiatric Clinic, General Hospital of Corfu, Corfu and [3]Psychiatric Clinic, University General Hospital of Ioannina, Ioannina, Greece
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.391

Introduction: Psychiatric disorders,such as anxiety,depression, bipolar disorder and schizophrenia,remain major global health challenges. Although prevalence has not recently increased, mental health care struggles with early diagnosis, real-time monitoring and personalized treatment. Traditional methods, relying on self-reports and clinical assessments,often miss the dynamic nature of these conditions.AI and wearable technology offer a new approach, enabling continuous data collection and real-time analysis to improve early detection and optimize patient care
Objectives: This study aims to assess the role of AI-driven wearables in diagnosing,monitoring and managing psychiatric disorders by:
Evaluating AI's effectiveness in predicting psychiatric episodes using wearable sensor data
Exploring clinical applications to improve patient outcomes
Identifying challenges and ethical considerations in the broader use of this technology in mental healthcare
Methods: A systematic review of studies(2018-2023)on AI and wearable technology in psychiatry was conducted using PubMed, Scopus and Google Scholar.Studies were selected based on their focus on AI-driven wearables for predicting or managing psychiatric conditions.These devices typically captured physiological and behavioral data,such as heart rate variability,sleep patterns and movement.The accuracy of AI algorithms in predicting psychiatric episodes was compared to traditional methods,with statistical analysis used to assess outcomes
Results: The review showed that AI-driven wearable devices significantly improved early detection and prediction of psychiatric episodes,with accuracy rates over 80% for depression, anxiety and bipolar disorder.Wearables,combined with AI algorithms, effectively monitored physiological data like heart rate and sleep patterns,providing real-time insights for personalized, timely interventions.For example,changes in sleep and activity levels,alongside heart rate variability,strongly predicted depressive episodes.In patients diagnosed with bipolar disorder,AI detected mood swings early by analyzing behavioral data from wearables,enabling stabilization.Wearables also helped monitor medication adherence and reduced relapse rates in patients diagnosed with schizophrenia by identifying early signs of psychotic episodes
Conclusions: AI-driven wearable technology has the potential to transform psychiatric care by enabling continuous monitoring and personalized interventions.These tools enhance early detection and prediction of psychiatric episodes,offering a more dynamic approach than traditional methods.However,challenges such as data privacy, ethical concerns and the lack of regulatory frameworks must be addressed before widespread clinical use.Further research is needed to refine AI algorithms,validate the long-term effectiveness of wearables and ensure patient safety through regulations and privacy protections

The Association Between Occupation, Attitudes Towards Mental Health Problems in the Workplace and Mental Health Stigma

G. Cheung[1,2]*, A. Ronaldson[3] and C. Henderson[3]

[1]Hull York Medical School; [2]York and Scarborough Teaching Hospitals NHS Foundation Trust, York and [3]Centre for Implementation Science,

Health Service and Population Research Centre, Institute of Psychiatry, Psychology, & Neuroscience, King's College London, London, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.392

Introduction: Although mental health problems are common in the workplace, discrimination against mental health is still prominent. Characteristics of one's own occupation can influence aspects of stigma and attitudes to mental health problems in the workplace context, but there are limited studies examining differences in them between occupational groups.
Objectives: We investigated occupational differences in mental health stigma, and attitudes to both mental and physical health in the workplace.
Methods: Data from the British Social Attitudes 2015 survey were used. Logistic regression models were conducted to investigate associations between occupational categories and stigma as measured by desire for social distance, as well as attitudes towards mental and physical health in the workplace. Occupational categories were based on the National Statistics Socio-economic Classification. Measures for attitudes to mental and physical health in the workplace include whether paid work is good for mental and physical health, how soon one should return to work following depression, whether work can help speed recovery from depression, whether one's medical history should affect their promotion, including depression, schizophrenia and diabetes. Desire for social distance from people with depression and schizophrenia was measures using unlabelled vignettes.
Results: We found occupational differences in attitudes towards mental and physical health in the workplace, but not in levels of stigma. People in lower supervisory and technical (group 4), semi-routine and routine (group 5) occupations were more likely to have negative attitudes towards mental and physical health in the workplace compared to managerial and professional occupations (group 1). Both occupation groups were less likely than group 1 to believe that paid work is good for mental health (group 4: odds ratio (OR) = 0.38, 95% confidence interval (CI) = 0.24-0.61; group 5: OR = 0.34, 95% CI = 0.24-0.49). They were also less likely to believe that people with depression should return to work when they can do some or most of the job (group 4: OR = 0.67, 95% CI = 0.48-0.94; group 5: OR = 0.52, 95% CI = 0.41-0.66). People in group 5 were less likely to believe that paid work is good for physical health (OR = 0.69, 95% CI = 0.53 to 0.89) and that having schizophrenia should not affect promotion at work (OR = 0.78, 95% CI = 0.62-0.97) than group 1.
Conclusions: Our study reinforced the importance of job characteristics on attitudes to mental health in the workplace. First, employers need to invest more in improving their employees' well-being. Second, governments should provide more support and resources for small companies to help them develop mental health policies and practices. Third, modifications need to be made to improve job control for employees and to ensure enough reasonable adjustments can be made.

EPP032

Selective outcome reporting and non-reporting in trials of psychedelic drugs for mental disorders

I. A. Cristea[1]*, G. Tomei[1], J. Freddi[1] and A. Bonessio[1]
[1]General Psychology, University of Padova, Padova, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.393

Introduction: Selective reporting of outcome data (SOR) refers to trialists selecting results for publication based on the results of a subset of the initially measured outcomes. SOR for specific, potentially very profitable, treatments, particularly in key junctures such as in the period leading to or immediately preceding approval, has not been examined.
Objectives: We examined the prevalence and types of SOR for three of the most prominent psychedelic drugs, either approved by regulators or considered very close to approval: esketamine, psilocybin and MDMA.
Methods: We used a publicly available inception cohort (https://osf.io/yfv9n) of intervention trials of psychedelic drugs that were registered on clinicaltrials.gov by March 2023. We selected randomized trials in participants with symptoms, a diagnosis or risk of mental disorders. Trials had to assess the efficacy of esketamine, psilocybin or MDMA, alone or in combination with other treatments, compared to any control or active intervention, and include at least one efficacy outcome.
Results: We identified 98 randomized trials, 56 of which had a clinicaltrials.gov status of completed, terminated or unknown as of July 2024. Sixteen of 56 (28.5%) had no publication available as well as no results posted on clinicaltrials.gov. Of these sixteen, seven were described as completed in the registry (three had a completion date in 2022, two in 2023). Another 8 trials we described as unknown, with anticipated completion dates ranging from 2021 to 2023. For 29 trials (51%) we could identify peer-reviewed publications. Five other trials had only been published as conference posters or company press-releases. Of the 29 trials matched with publications, the primary outcome measure had been changed in 2 (7%), with an outcome initially registered as secondary upgraded to primary. There were changes regarding the timepoint of assessment for the primary outcome in 7 trials (24%): in 4 trials the timepoint had been changed, while in 3 trials, the publication only reported on a subset of the timepoints registered for the primary outcome.
Conclusions: Selective reporting and non-reporting of study results are present in trials of the most prominent psychedelic drugs, but given the scarce information contained in clinical trial registries, they are difficult to assess. Full access to all time-stamped versions of trial protocols and statistical analysis plans would be necessary to gauge the extent and types of SOR, including changes to the analysis method.

Workplace and non-workplace loneliness: a comparative study on risk factors and impacts on absenteeism and mental health among employees in Spain

J. Domènech-Abella[1]*, C. Muntaner[2], J. Mundó[3] and J. M. Haro[4]
[1]Parc Sanitari Sant Joan de Déu, Sant Boi de Llobregat (Barcelona), Spain; [2]University of Toronto, Toronto, Canada; [3]Universitat de Barcelona and [4]Parc Sanitari Sant Joan de Déu, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.394

Introduction: Loneliness can manifest in various aspects of life, including personal and professional contexts. Although most of studies on loneliness are focused on general loneliness without the specification on any context, the study of workplace loneliness has garnered increased attention in recent years and researchers explore how loneliness in professional settings affects labor satisfaction, productivity and mental health of workers. However, few studies have directly compared workplace and non-workplace loneliness, particularly in terms of their prevalence, agreement with each other, risk factors, and consequences
Objectives: The aim of this study is to (1) evaluate prevalences and concordance between workplace and non-workplace loneliness, (2) compare sociodemographic risk factors between workplace and non-workplace loneliness, (3) compare working conditions-related risk factors between the two contexts of loneliness, and (4) compare their impact on absenteeism, depression, anxiety and substance use disorder.er.
Methods: A representative sample of the employee residing in Spain (n=5400) was surveyed using computer-assisted web interviews (CAWI). Logistic regression models were constructed to compare the effects of risk factors for workplace and non-workplace loneliness (including sociodemographic factors, and factors related to working conditions), as well as the impact of workplace and non-workplace loneliness on absenteeism, and symptoms of depression, anxiety, and substance use disorder.
Results: 40,7% of active workers report experiencing workplace loneliness, while 42.0% report non-workplace loneliness. The level of concordance between both types of loneliness is low (k=0.36). Both types are more prevalent among younger workers and migrated people. Other sociodemographic risk factors (being female, non-married, and non-heterosexual) were significantly associated with non-workplace loneliness. Meanwhile, risk factors related to working conditions -particularly working under stress and labor precariousness- were associated with both types of loneliness, which showed an independent impact on absenteeism, depression, anxiety, and substance use disorder.
Conclusions: Most of social determinants of workplace loneliness are rooted in the work environment, indicating that effective interventions should focus on addressing labor conditions and precariousness to improve both workplace and non-workplace loneliness and their impacts on absenteeism and mental health.

Causal Relationship Between Social Isolation, Loneliness, and Cardiovascular Disease

Y. Nie[1], Y. He[2], J. Zhang[1] and Y. Y. Liang[1]*
[1]Center for Sleep and Circadian Medicine, The Affiliated Brain Hospital of Guangzhou Medical University and [2]Department of Medicine, The Third Affiliated Hospital of Sun Yat-Sen University, Guangzhou, China
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.395

Introduction: Cardiovascular disease (CVD) has become one of the leading causes of death worldwide. Psychosocial factors play a significant role in the pathogenesis of CVD. Social isolation and loneliness, two important aspects of social determinants, have been shown to be associated with adverse health outcomes. However, it remains unclear whether social isolation and loneliness increase the risk of CVD and exacerbate CVD development.
Objectives: This study aims to investigate 1) whether social isolation and loneliness are associated with CVD; 2) whether the associations between social isolation and loneliness and CVD are consistent with causal effects; and 3) whether social isolation exacerbates CVD development.
Methods: We capitalized on a large sample of individual-level data from the UK Biobank. Participants' levels of social isolation and loneliness were assessed via questionnaires. 6 cardiovascular diseases (atrial fibrillation, heart failure, hypertension, myocardial infarction, peripheral vascular disease, and stroke) were included by linking hospital admission data and death registry records. We used Cox proportional hazards models to estimate the hazard ratios (HRs) of social isolation and loneliness with the risk of CVD. Additionally, we employed two-sample Mendelian randomization analysis to estimate the causal relationships between social isolation, loneliness, and CVD. Finally, we evaluated the impact of social isolation on the clinical outcomes of myocardial infarction in mice. We determined infarct size using histology and heart function using echocardiography.
Results: During a median follow-up of 12.6 years, after adjusting for demographic, socioeconomic, and lifestyle factors, most isolated group was associated with an increased risk of 4 out of 6 cardiovascular diseases compared to the least isolated group: heart failure, peripheral vascular disease, stroke, myocardial infarction, and hypertension. Loneliness increased the risk of all 6 cardiovascular diseases. Two-sample Mendelian randomization analysis showed that fewer leisure or social activities was associated with an increased risk of stroke (OR 1.01; 95% CI 1.00-1.02). Loneliness was associated with an increased risk of heart failure (OR 1.70; 95% CI 1.13-2.57), myocardial infarction (OR 1.02; 95% CI 1.00-1.04), and atrial fibrillation (OR 1.00; 95% CI 0.99-1.00). Further, compared to group-housed mice, socially isolated mice showed significantly reduced cardiac ejection function, increased myocardial fibrosis and cardiomyocyte apoptosis after myocardial infarction.
Conclusions: Potential causal relationships were identified between genetic liability to social isolation, loneliness and the incidence of cardiovascular diseases. Social isolation may exacerbate the progression of myocardial infarction. The results of this study emphasize the adverse impact of social disconnections on the incidence and development of cardiovascular diseases.

The forensic assessment of urgent involuntary psychiatric admissions in Barcelona (Spain)

J. Casanovas[1]*, A. Martínez[1], C. Fuentes[1], M. Vilella[1], E. Barbería[1,2] and A. Xifró[1,3]

[1]Institut de Medicina Legal i Ciències Forenses de Catalunya, Barcelona; [2]Universitat Rovira i Virgili, Reus and [3]Universitat de Barcelona, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.396

Introduction: In Spain, involuntary admission due to mental disorder requires judicial authorization, which can be prior or, in cases of urgency, immediately subsequent. The courts routinely request an independent medical expert opinion in these cases.
Objectives: Our aim was to determine the current results of these evaluations and the characteristics of the patients assessed.
Methods: Retrospective study from January 1 to June 30, 2023 in the city of Barcelona. The source of information were the case records at the Institute of Legal Medicine and Forensic Sciences of Catalonia. The inclusion criteria were: psychiatric involuntary admission, urgent, and assessment by the forensic doctor assigned to the courts. Sociodemographic, clinical and forensic data were collected.
Results: In the 181 days between January 1 and June 30, 2023, 1,151 forensic medical assessments of urgent hospitalizations were recorded in Barcelona (on average 6.4 per day). Of these, 849 (73.8%) were included. In all of them, the forensic medical report concluded that hospitalization was rightly indicated. The admissions were carried out in 14 different health centers. The psychiatric acute inpatient wards of the city's main general hospitals received the vast majority of cases. The patients were mostly men (n=483; 56.9%). The average age was 38.2 years (s.d. 16.99), with no differences between sexes. 13.5% (n=115) were minors, with female predominance (n=79; 68.7%). 6.9% (n=59) were 65 years of age or older, also with a female predominance (n=39; 66.1%). In minors, affective disorders (n=37; 32.7%) or eating behavior disorders (n=32; 28.3%) stood out, while in the group from 18 to 65 years of age the main diagnostic group were psychotic disorders (n =491; 73.1%). The latter were also the majority after 65 years of age (n=35; 59.3%), followed by affective disorders (n=16; 27.1%). Globally, psychotic disorders were the most frequent diagnostic group for both men (n=346; 71,9%) and women (n=188; 51,8%). Affective or eating behaviour disorders accounted for 35,8% of women (n=130) and 18,3% of men (n=88).
Conclusions: The forensic assessment of the medical indication of urgent involuntary psychiatric hospitalizations coincides with the clinical assessment. Patients with this measure show differential characteristics according to age in terms of gender and diagnosis. More men are involuntarily admitted than women for most of the adult stage, while the reverse is true at both extremes of the lifespan. Also, involuntarily admitted women show a higher frequency of mood or eating behaviour disorders than men.

EPP037

Impact of early child-parent bonding on violence in patients with schizophrenia

X. Ling[1,2]*, S. Wang[1], N. Li[3], Q. Zhang[1] and H. Li[1]

[1]Shanghai Key Lab of Forensic Medicine, Key Lab of Forensic Science, Ministry of Justice, Shanghai Forensic Service Platform, Academy of Forensic Science; [2]Department of Forensic Medicine, School of Basic Medical Sciences, Fudan University and [3]Shanghai Hongkou Mental Health Center, Mental Health Center Affiliated to Shanghai University School of Medicine, Shanghai, China
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.397

Introduction: Violence is a major global health concern among patients with schizophrenia. However, the triggers of violent behavior remain unclear. In previous studies, familial risk factors are believed to be associated with mental disorders and violence. The relationship between parental bonding or childhood adversity and psychopathologic behavior (such as violence) has rarely been evaluated.
Objectives: The study aimed to explore the relationship between violent behavior and childhood experience and to determine the role of the early child-parent bond in violence risk in patients with schizophrenia.
Methods: The study enrolled 287 patients with schizophrenia and 100 healthy controls. Patients were divided into 3 groups: patients with homicidal history (Group A), patients with violent behavior and without homicidal history (Group B) and patients without violent behavior (Group C). Childhood trauma questionnaire (CTQ), parental bonding instrument (PBI) and modified overt aggression scale (MOAS) were used to explore the violent behavior and childhood experience. All individuals participated voluntarily and provided informed consent. This study was approved by the ethics committee of the Academy of Forensic Science.
Results: The findings indicated the proportion of males to be higher in the patient groups than in the healthy controls, especially in the group with homicidal history. Patients had a significantly higher prevalence of sexual abuse, emotional abuse and emotional neglect than the healthy controls. The emotional abuse and emotional neglect were found to be positively and negatively related to MOAS scores. Maternal over protection was found to be negatively related to the MOAS scores. On the CTQ subscales, emotional neglect was significantly associated with violence risk (OR=1.13, 95% CI=1.04–1.22). On the PBI subscales, maternal and paternal care (0.84, 0.74–0.94 and 1.30, 1.13–1.49) and over protection (1.18, 1.07–1.29 and 0.87, 0.81-0.95) were found to be significantly associated with violence risk. Maternal and paternal over protection were significantly associated with homicide risk (0.87, 0.78-0.97 and 1.10, 1.01-1.20).
Conclusions: The schizophrenia patients with violence might suffer lower paternal care and emotional abuse during the childhood. In terms of violence in schizophrenia patients, paternal over protection and maternal care might be a protective factor and emotional neglect, maternal over protection and paternal care might be a risk factor. In terms of homicide in schizophrenia patients, paternal over protection might be a risk factor and maternal over protection might be a protective factor. Therefore, childhood trauma and parental care and over protection could be a potential reference indicator for assessing violence risk in patients with schizophrenia.

EPP038

Self-harm and suicide risk amongst attendees at five lower courts in London, England

J. McCarthy[1]*, E. Chaplin[1], C. Allely[2] and A. Forrester[3]

[1]London South Bank University, London; [2]University of Salford, Manchester and [3]Cardiff University, Cardiff, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.398

Introduction: Individuals in contact with the criminal justice system are at higher risk of suicide than the general population (Carter et al. EClinicalMedicine 2022, 44, 101266). Research to date has concentrated on the prison population with little evidence on the risk of suicide and self-harm for those defendants within the Court system including those referred to the Court Mental Health Liaison and Diversion Services. Court Mental Health Liaison and Diversion services were developed in England to support vulnerable people when they first come into contact with the criminal justice system.
Objectives: The main aim of the study was to analyse the existing service data to examine rates of self-harm behavior and suicide ideation of those defendants presenting to the Court Mental Health Liaison and Diversion Services across five Magistrates Courts (lower courts) in London, England. In addition, a further aim was to establish if risk factors such as mental illness and substance misuse but also other vulnerabilities such as neurodevelopmental disorders are associated with the risk for self-harm behaviour or suicide along with demographic factors of age, gender and ethnicity.
Methods: The study analysed service level data of five London Magistrates' Courts covering a timeframe from September 2015 to April 2017. During this time 9088 attendees were referred to the Court Mental Health & Liaison Diversion service covering the five courts. Attendees were screened for current risk of suicide ideation and self-harm behaviour as part of the mental health assessment. Data examined was from the National Health Service (NHS) minimum mental health data set which reflects current clinical and custody records and is obtained from frontline court and health service staff.
Results: An overall rate of 14.2% for self-harm behaviour and/or suicide ideation was found for attendees presenting to five London Court Liaison and Diversion Services over a 20-month time frame. Aside from autism and bipolar affective disorder, the current large study showed a significant association between self-harm behaviour and suicide ideation with several mental disorders. The study found no significant differences for risk of self-harm behaviour and suicide ideation relating to gender or ethnicity.
Conclusions: This group of defendants presented with high levels of severe mental illness, substance and alcohol misuse and neurodevelopmental disorder which increased the individual vulnerability to express suicidal ideation as has been found in smaller studies. The wider criminal justice services need to examine the current approach to screening for risk of suicide ideation and self-harm behaviour given the high rates of completed suicide within the prison population compared to the general population.

Mapping Forensic Psychiatry Education Across Europe: Insight from EFPT members

F. M. Monshizadeh Tehrani[1]*, B. Akan[1], B. Özel[1], S. Kukurt[1], E. Ilgin[1], V. H. Santos[1], M. Nouri[2], D. Zani[1], K. Krasteva[1], P. Viktorova[1], M. Godschalk[1], G. Autissier[1], A. Compaired[1], F. Mustač[1], L. Sanduleac[1], O. Nikolaieva[1], D. A. Zaharie[1], J. Halili[1], A. Avalishvili[1], G. Longo[1], N. De Ridder[1], A. Braicu[1] and S. Shokatpour[3]

[1]Forensic Psychiatry Working Group, European Federation of Psychiatric Trainees, Brussels, Belgium; [2]Zanjan University of Medical Science, Zanjan and [3]Faculty of Psychology and Educational Sciences, Islamic Azad University, Islamshahr Branch, Tehran, Iran, Islamic Republic Of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.399

Introduction: Forensic psychiatry transcends legal and cultural boundaries across Europe, but specialization and training remain inconsistent. With freedom of movement in most European countries, psychiatrists accredited in one country can practice in others if they meet language requirements. Therefore, harmonizing psychiatric education and practice is crucial and aligns with the European Federation of Psychiatry Trainees (EFPT)'s goals.
Objectives: This study aims to map the current state of forensic psychiatry education across Europe, focusing on its recognition as a specialty on its own or subspecialty, training structure, and financial implications. It also assesses whether general adult psychiatry (GAP) and child and adolescent psychiatry (CAP) trainees receive adequate forensic psychiatry education, identifying gaps and variations across countries.
Methods: Data was collected via an online survey distributed to European National Trainee Association (NTA) representatives in the EFPT through Google Forms in August 2024. Responses from non-European countries and incomplete entries were excluded. The final dataset was analyzed using SPSS 24.
Results: A total of 29 participants, including 24 GAP trainees (82.8%), 2 CAP trainees (6.9%), and 3 specialists (10.3%), from 20 European countries responded to the survey. Forensic psychiatry was recognized either as a specialty or subspecialty in 13 counctries (65%) with 20 (69%) of participants confirming its recognition. 38% reported forensic training lasts less than 1 year or lacks a formal program. Financial support varied as well, with some countries offering full subsidies, while others required trainees to cover costs. Forensic psychiatry was included in the training of 66.7% of GAP trainee and 50% of CAP trainees, though the depth of

exposure differed. Notable gaps were found particularly in risk assessment, expert witness training, and competency evaluations.
Conclusions: This study reveals significant variation in the recognition, structure, and delivery of forensic psychiatry training across Europe. While some countries offer well-defined programs, discrepancies in accessibility and comprehensiveness persist. These findings highlight the need for standardized curricula to ensure consistent training. Enhancing forensic psychiatry education is crucial for preparing future psychiatrists and ensuring high-quality psychiatric contributions in legal contexts and harmonization of forensic training across Europe.

Biological pathways mediating the relationship between climate change, environmental pollutants, and severe mental disorders: a systematic review

P. Catapano[1]*, S. Cipolla[1], N. P. Sallusto[1], C. Lamberti[1], R. Murolo[1], G. Sampogna[1] and M. Luciano[1]

[1]Department of Psychiatry, University of Campania "Luigi Vanvitelli", Naples, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.400

Introduction: Climate change and pollution are deeply interconnected phenomena that pose significant risks to overall health, given their proven impact on the functionality of various human organs and systems. With increasing urbanization, global toxicity is expected to rise in the near future. It is therefore crucial to understand how environmental pollution affects mental health, particularly in rapidly growing urban areas.
Objectives: This systematic literature review aims to explore the biological mechanisms linking exposure to environmental pollutants, climate change, and the onset and/or exacerbation of severe mental disorders.
Methods: A search was conducted in the PubMed, Scopus, and APA PsycInfo databases, following PRISMA guidelines. Studies on humans and animal models examining the association between environmental pollutants, climate change, and mental disorders were included. A total of 48 articles were considered, comprising studies on humans (16 studies) and animal models (31 studies), along with one article that included both models.
Results: Human studies revealed that exposure to particulate matter (PM 2.5 and PM10) increases the risk of depression and psychotic relapses through mechanisms involving inflammation, oxidative stress, and disruption of the hypothalamic-pituitary-adrenal axis. In animal models, pollution was shown to impact brain function by activating inflammatory responses, causing oxidative stress, damaging the hippocampus, and dysregulating neurotransmitters. Additionally, one study highlighted that climate change is associated with mood disorders by inducing changes in gene expression and psychophysical adaptation responses.
Conclusions: The findings indicate that environmental pollutants and climate change can affect human mental health through complex biological pathways. Understanding these mechanisms is essential for developing prevention and intervention strategies. The One Health approach, which recognizes the interconnectedness of human, animal, and environmental health, is crucial for addressing the challenges posed by climate change and pollution.

doi: 10.1192/j.eurpsy.2025.401

Introduction: Migration, whether legal or illegal, is a growing phenomenon in Tunisia and can bring significant mental health challenges. Migrants often experience a decompensation of pre-existing psychiatric disorders, the development of new mental health issues, or travel driven by a delusion, known as "pathological travel." These concerns emphasize the need for specialized psychiatric and social care for this vulnerable group, who endure considerable stress throughout their migration. However the quality of care can also depend on the support from their home countries, where stigma and identification issues with consulates can limit their access to help.
Objectives: To study the different psychiatric pathologies observed among this population and to determine the number of cases of pathological travel.
Methods: It's a retrospective study. We reviewed the files of all patients who were hospitalized in the Avicenne Psychiatric Department of Razi Hospital between January 2022 and December 2023.
Results: We identified 19 patients and found 17 files. There were 11 men and 6 women, with an average age of 33 years (ranging from 20 to 54 years). The majority have a university-level education (52%) and with a history of psychiatric illness (58%). In total, 41.2% were from the Maghreb, 41.2% from Africa, 11.7% from Europe, and 5.9% from the Americas. The causes of migration to Tunisia were, for economic reasons (29%), for studies (11%), for seeking treatment for a pre-existing psychiatric condition (11%), marriage to a Tunisian partner (11%) and as part of a pathological travel (34%). In 35% of cases, the migration was clandestine and illegal. The reason for hospitalization was behavioral disorder in 64.8%, incoherent speech in 29.4% and suicide attempt in 5.8%. Among our patients, 28% have bipolar disorder, 17% have schizophrenia, 11% have brief psychotic disorder, 5% have depression, 5% have schizoaffective disorder, 5% have delusional disorder, and 5% alcohol use disorder. The diagnoses for the rest of patients were unspecified. In terms of social support we were able to contact the families in 62% of the cases. We succeeded in getting a response from the consulate of the native country in 17% and we collaborated with an International Organization in 5%.
Conclusions: Our study shows the complex psychiatric needs of migrants in Tunisia, with a range of mental health disorders, including cases of pathological travel. Economic reasons and clandestine migration were common factors. Despite efforts, social

support remains limited, with minimal consular and organizational collaboration, economic challenges, emphasizing the need for stronger international and social support systems.

Nomadic souls: Exploring the Mental Health Journey of Migrants through Art

S. Regev[1]*, V. Gailis[2] and A. Smoliarova[3]

[1]Occupational Therapy, Ben Gurion University of The Negev, Be'er Sheva; [2]Vera Gailis - independent art curator, Haifa and [3]Center for Germant Studies, Hebrew University of Jerusalem, Jerusalem, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.402

Introduction: *Nefashot*, meaning "Souls" and "People" in Hebrew, is an initiative dedicated to promoting mental health awareness through cultural and artistic expressions, fostering inclusive dialogue. Art serves as a critical tool in this mission, using its visual language to make difficult conversations possible and amplify voices that are often unheard.
Objectives: The "Nomadic souls" project aims to raise awareness about the intersection of migration and mental health through the presentation of high-quality contemporary art in exhibitions, curated by professional curators and researchers. By showcasing diverse artistic perspectives, it seeks to foster deeper understanding and dialogue around these critical issues.
Methods: This project is a collaboration between *Nefashot*, the art initiative *KAKDELART*, and curators Vera Gailis and Anna Smoliarova, who together launched a call for Israeli artists with diverse immigrant backgrounds under the theme "Nomadic Souls." The call invited artworks exploring the connection between migration and mental health. So far, the project has produced two exhibitions: "Being Singular/Plural," which centered on the concept of belonging, and "A Semiotics of the Start," which delved into the experience of language acquisition. Each exhibition was accompanied by events like literature readings, artist networking, and pop-up photo exhibitions, fostering community engagement and inclusivity.
Results: The project made significant strides in building collaborations and laying the foundation for a platform that facilitated discussions on migration and mental health within both immigrant and local communities. It successfully increased public awareness of these issues and established sustainable partnerships that continued to support the community. Community engagement was central to the project. The exhibitions and related events actively involved migrants as participants, artists, and audience members. Collaborations with the city's youth department for immigrant assistance were crucial, including co-funding an event that attracted a relevant and engaged audience. Beyond the exhibitions' objecthood, the project addressed deeper issues such as suicide, anxiety, and depression. Additionally, an academic webinar with immigration professionals was held, focusing on the second exhibition catalog, further broadening the project's impact and reach.

Image 1:

Conclusions: The *Nefashot* initiative highlights the power of art and community collaboration in addressing complex mental health issues related to migration. By fostering dialogue and partnerships, the project has expanded its reach, connecting both local and migrant communities in meaningful ways. The ongoing and future exhibitions aim to continue this momentum, establishing a lasting platform for dialogue, collaboration, and support.

Barriers towards mental health service utilization among religious immigrants

R. Whitley[1]* and G. E. Jarvis[1]

[1]Psychiatry, McGill University, Montreal, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.403

Introduction: Evidence suggests that immigrants and minorities with mental distress underuse mental health services compared with the majority population. Such under-utilization, combined with other socio-cultural factors, can impede recovery from mental illness. The population of Canada is becoming increasingly diverse, primarily due to record levels of immigration. These immigrants come from a variety of traditions including Muslim, Christian, and Jewish backgrounds. For such immigrants, their religious beliefs, practices and activities are often central to their lives and influence important decisions regarding health and well-being. These changing demographics have prompted calls for more research and action regarding the mental health service experience of religious immigrants.
Objectives: The objective of this study was to identify and understand self-identified barriers to mental health service utilization

among religious immigrants, including eliciting experiences within the mental health care system.
Methods: To meet these aims, we employed a qualitative community-based approach, conducting in-depth semi-structured interviews with 58 first- or second-generation immigrants to Canada who identified as people of religious faith, comprising Christians, Muslims and Jews. All participants had used a mental health service in recent years, and they reported a variety of mental disorders, mostly depression and anxiety. Interviews were transcribed and data was analyzed using thematic analysis techniques.
Results: Analysis revealed three core barriers to service utilizations. First, participants often reported that some people in their social circle (such as parents and clergy) held stigmatizing views of mental illness, including sceptical views about the reality of mental illness. This contributed to self-stigma, inhibited disclosure and delayed help-seeking. Second, participants stated that service providers typically had a very limited understanding of the cultural and religious context of their lives, and sometimes conveyed a dismissive or ignorant attitude towards their deeply-held religious beliefs and practices. This negatively affected service utilization and the development of a therapeutic alliance. Third, some participants noted that they (and other members of their communities) lacked knowledge about mental illness, available treatments, and effective therapies, meaning they were unaware of potential services and supports.
Conclusions: The results suggest an urgent need for a multi-pronged approach to better engage religious minorities with mental distress. On the clinical side, there is a need for more religious and cultural competence training for Canadian clinicians. On the community side, culturally-appropriate anti-stigma and mental health literacy interventions may need to be co-created and implemented in partnership with different immigrant communities in Canada.

Clinical and Psychosocial Variables Associated to Higher Costs in Schizophrenia Spectrum Disorders

I. Calzavara-Pinton[1,2]*, L. Bertoni[3], L. Altieri[3], D. Zardini[3], N. Necchini[3], S. Paolini[3], A. Baglioni[3], A. Cicale[3], M. Italia[3], G. Nibbio[3], S. Barlati[3] and A. Vita[3]

[1]Department of Biomedical Sciences and Translational Medicine, University of Brescia; [2]Department of Mental Health, ASST Spedali Civili di Brescia and [3]Department of Clinical and Experimental Sciences, University of Brescia, Brescia, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.404

Introduction: In Italy, in 2000, the estimated annual economic burden of schizophrenia was 25.000 € per patient, of which 30% were direct costs and 70% indirect costs (Tarricone et al., 2000). Yet, a steep growth has been observed throughout the years: a study showed a yearly expenditure of 41.290 € per patient in 2020 (Latorre et al., 2022).
Objectives: The aim of this study was to better characterize the association between direct costs and clinical and psychosocial variables in schizophrenia spectrum disorders (SSD).
Methods: A total of 276 individuals with schizophrenia spectrum disorders receiving treatment from the Community Mental Health Centers of Brescia (Italy) were included in the study: for each participant socio-demographic, clinical and functional characteristics were assessed, and data related to the use of services in 2022 (then converted to costs) were collected. Clinical and functional characteristics were assessed using the Clinical Global Impression-Severity (CGI-S) scale, the Personal and Social Performance Scale (PSP) scale and the Positive and Negative Syndrome Scale (PANSS). Correlations between the included variables were performed using SPSS v28; values of $p < 0.05$ were considered statistically significant.
Results: Our analyses identified a direct healthcare expenditure of 16477.23 € per patient per year. A positive correlation was observed between higher costs and higher scores at the CGI-S ($p<0.001$), the PANSS total ($p<0.001$) and all the PANSS subscales (all $p<0.001$). Moreover, a negative correlation between higher costs and age of onset ($p=0.010$) and PSP total score ($p<0.001$), were observed.
Conclusions: An earlier age of onset, a more severe clinical presentation and a worse psychosocial functioning are associated to a higher expenditure in terms of direct costs associated to use of services in SSD. These results prompt to the implementation of interventions that aim at improving not only clinical aspects, but also functional ones: a full functional recovery would not only benefit patients, but also lead to a lower impact of SSD on healthcare systems. One limitation of the present study is that the estimation of the costs was based on a direct analysis of costs related to the use of services, therefore excluding indirect costs. Future studies should include data on pharmacological treatments, comorbidities and other clinical variables central to the disorder, such as cognition.

The Role of Religiosity in Anxiety and Life Satisfaction: Insights from Sociodemopgraphic Data

E. D. D. Cindik-Herbrueggen

Psychiatry, Neuro-Psychiatric Center, München, Germany
doi: 10.1192/j.eurpsy.2025.405

Introduction: The connection between well-being and various sociopsychological factors such as age, gender, education level, and more is a growing and significant area of interest in today's studies.
Objectives: The aim of this study is to examine the relationship between sociodemographic factors, life satisfaction, levels of anxiety, and religiosity. To achieve this goal, the study explored whether religiosity has an effect on anxiety and life satisfaction on the one hand, and whether sociodemographic variables influence the centrality of religion in participants' lives on the other.
Methods: To ensure honest responses, the surveys were filled out anonymously. Statistical analyses were conducted using the SPSS program, applying Pearson Correlation and Analysis of Variance

(ANOVA) to determine if there was a correlation between sociodemographic data and questionnaire scores.
Results: In the Analysis of Variance (ANOVA) of total STAI-G scores and religiosity, a significance level of 0.010 was observed, while the Post-Hoc Test suggested that this significance may be found between atheist participants and those who identified with a religion other than Islam, Christianity, or Judaism, with a value of 0.019. Additionally, there is a strong significant correlation of 0.018 between participants' native language and total CRS-10 scores, which may imply that native language, encompassing important factors like cultural background, can influence participants' religious beliefs and practices. Lastly, a significant correlation of 0.041 was found between alcohol consumption and total CRS-10 scores. This correlation could indicate that religious participants are more likely to consume less alcohol compared to non-religious participants, possibly due to their religious beliefs.
Conclusions: This study highlights the importance of examining the connections between sociodemographic factors, life satisfaction, anxiety, and religiosity in relation to mental well-being. The findings aim to provide useful guidance for the evolution of interventions that focus on and enhance well-being and continuity, while emphasizing the quality of life experienced by patients from diverse cultures and backgrounds.

ADHD and Decision Paralysis: Overwhelm in a World of Choices

B. A. Oroian[1]*, P. Nechita[2] and A. Szalontay[1,2]

[1]"Grigore T. Popa" University of Medicine and Pharmacy Iasi and [2]"Socola" Institute of Psychiatry Iasi, Iasi, Romania
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.406

Introduction: Decision paralysis, defined as the inability to make decisions due to overwhelming options or uncertainty, is an often overlooked symptom of Attention-Deficit/Hyperactivity Disorder (ADHD). Individuals with ADHD frequently struggle with executive dysfunction, making it difficult to prioritize tasks, evaluate choices, and make timely decisions. Despite its significance, decision paralysis remains under-researched, particularly in terms of its impact on daily functioning and quality of life.
Objectives: This study aims to assess the prevalence and severity of decision paralysis in adults with ADHD, explore its relationship with executive dysfunction, and analyze its impact on various life outcomes such as career performance, interpersonal relationships, and overall well-being.
Methods: A total of 50 adults diagnosed with ADHD participated in this study. Self-report measures, including the Decision-Making Competence (DMC) scale and the ADHD Executive Dysfunction Questionnaire (AEDQ), were administered to assess participants' decision-making difficulties, indecision, and executive functioning. Additional data were collected on life satisfaction, perceived stress levels, and the degree of daily functional impairment due to decision paralysis.
Results: The results indicate that 82% of participants reported frequent difficulties with decision-making, with 68% indicating that decision paralysis significantly affected their work performance. Decision paralysis was strongly correlated with executive dysfunction scores and was a significant predictor of reduced life satisfaction and increased perceived stress. Additionally, 74% of participants reported that indecision contributed to delays or avoidance in making important life choices, such as career changes or financial decisions, leading to long-term dissatisfaction. Notably, 58% of participants experienced decision paralysis at least once a week, with 35% reporting daily occurrences. Furthermore, 61% of participants indicated that decision paralysis led to missed opportunities in both personal and professional contexts, contributing to feelings of regret and frustration.
Conclusions: This study highlights the widespread impact of decision paralysis in adults with ADHD, significantly affecting both personal and professional domains. The strong correlation between decision paralysis and executive dysfunction suggests that addressing this symptom could be critical in improving quality of life for individuals with ADHD. Further research is needed to explore the development of specific interventions targeting decision paralysis.

Assessing impact of passive virtual reality exposure intervention on physiological parameters in caregivers of individuals suffering from schizophrenia: A pilot study protocol

R. Verma[1]*, V. Patil[1], I. Dhyani[1] and S. Karna[1]

[1]Psychiatry, All India Institute of Medical Sciences, New Delhi, India
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.407

Introduction: Caregiving to individuals with schizophrenia is intensive, complex, and long lasting. In developing countries, the primary caregivers are family members who rarely receive adequate preparation for their role. The diversity and intensity of caregiving roles also may result in caregiver strain and burden. Interaction with nature even in form of hearing sounds have been found to reduce stress markers. Immersive Virtual Environments (IVEs) can result in restorative effects such as increased positive affect, decreased negative affect, and decreased stress.
Objectives: To assess and compare the effect of combined use of nature-based VR and nature-based sounds to nature-based sounds only on physiological parameters (heart rate, respiratory rate, oxygen saturation, systolic and diastolic blood pressure) in caregivers of individuals having schizophrenia.
Methods: Sixty caregivers (aged more than 18 years) of inpatients with schizophrenia as per Diagnostic & Statistical Manual (DSM-5) will be recruited with consecutive sampling. Caregivers should have been staying with patient for at least previous 1 year and have been staying in the ward for previous 7 days for at least 12 hours/day. Individuals with hearing or visual deficits, history of having received treatment for mental illness/epilepsy, or taking sleeping pills/sedatives/hypnotics/cough syrup currently would be excluded. Paid caregiver and those not willing to provide written informed consent would be excluded from the study. Data collection tools will include a semi-structured proforma for mentioning the

socio demographic details, checklist for observing physiological parameters (Heart Rate, Respiratory Rate, Oxygen Saturation, and Blood Pressure), Perceived Stress Scale (PSS), Pittsburg Sleep Quality Index (PSQI), Satisfaction with Life Scale (SwLS), Subjective stress on Visual analogue scale (VAS), User Satisfaction Evaluation Questionnaire (USEQ) and VR Experience Questionnaire (VEQ). Participants would be divided randomly into two groups with group 1 (n=30) individuals receiving only nature-based sounds intervention and those in group 2 (n=30) would receive combined nature-based VR and nature-based sounds intervention.
Results: Primary outcome will be change in physiological parameters using repeated measures ANOVA. Additional outcomes like acceptability and feasibility of the intervention will also be reported as descriptive data. Pearson's correlation will be done between scale scores and change in physiological parameters in different groups based upon nature of intervention, illness based or gender based.
Conclusions: The study provides insight into the utility of upcoming VR interventions to cater the needs of caregivers to individuals with schizophrenia in moderating the stress levels.

Impact of Childhood Trauma on Stress Levels in Chronic Fatigue Syndrome Patients

Y. Dooms[1,2*], M. Van Den Houte[1,2], I. Coppieters[1,3,4], E. Vergaelen[1], S. Claes[1], K. Bogaerts[2] and L. Van Oudenhove[1]
[1]KU Leuven, Leuven; [2]UHasselt, Hasselt; [3]VUB, Brussels and [4]Maastricht University, Maastricht, Belgium
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.408

Introduction: Chronic Fatigue Syndrome (CFS) is marked by physical and cognitive fatigue, as well as increased susceptibility to fatigue. While the precise causes of CFS remain unclear, there is growing interest in the role of the stress response system in its development.
Objectives: Given that early adverse experiences might affect one's ability to handle stress effectively, the aim of this study was to examine whether such early life events could predispose patients with CFS to higher self-reported stress levels when confronted with psychosocial stressor.
Methods: 76 patients with CFS and 45 healthy controls (HC) underwent the Maastricht Acute Stress Test (MAST) to induce stress. Subjective stress levels were assessed before, during and after the task. The Childhood Trauma Questionnaire (CTQ) was used to retrospectively evaluate abusive and neglectful experiences in childhood
Results: Patients with CFS reported significantly higher levels of subjective stress at all stages of the MAST compared to HC (main effect of group; $p<0.0001$). Additionally, CFS patients had higher CTQ scores than HC ($p=0.04$). Within patients, higher levels of childhood trauma was associated with higher levels of self-reported stress ($p = 0.0047$) throughout the MAST. The results of the link are visualized in the attached figure.
Image 1:

Conclusions: Patients with CFS experience heightened stress levels during a validated stress-inducing task compared to HC. Furthermore, a history of greater childhood abuse and neglect is associated with increased stress levels later in life, potentially contributing to the development of CFS.

Evaluating the Effectiveness of Culturally Adapted Persian-Translated PEERS® (Program for the Education and Enrichment of Relational Skills) for Young Adults with ASD : A Mixed-Methods Study

M. Motamed[1*], J. Alaghband-rad[1], S. Jamaloo[1], N. Tavakkolian[1], R. Amin[2] and N. Khosravanmehr[2]
[1]Psychiatry, Tehran University of Medical Sciences and [2]Psychiatry, Iran University of Medical Sciences, Tehran, Iran, Islamic Republic Of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.409

Introduction: Social deficits are a significant impairment in adult ASD, leading to difficulties in socio-emotional cognition, communication, and relationships. Effective social skills interventions are crucial during the transition to adulthood. The UCLA PEERS® (Program for the Education and Enrichment of Relational Skills) for young adults is a prominent and well-researched intervention, implemented in over eighty countries and translated into numerous languages. This program includes concurrent sessions for young adults and their parents, aiming to improve social skills and reduce ASD-related social issues
Objectives: The current study aimed to test the effectiveness of a culturally adapted Persian -translated version of PEERS® for young adults with ASD without intellectual disabilities.

Methods: Three psychiatrists and two psychologists underwent PEERS® training and translated the manual into Farsi, adapting it culturally for Iran. Twenty-four young adults with ASD and their parents participated in the study, randomly assigned to a treatment group or a control group. Inclusion criteria were males aged 18-30 years with an ASD diagnosis, predominant social difficulties, motivation to participate, and a family member acting as a social coach. Exclusion criteria included intellectual disability, major psychiatric conditions, and significant verbal or literacy difficulties. Participants attended 16 weekly 90-minute group sessions, covering topics like conversations, humor, electronic communication, dating etiquette, conflict management, and bullying. Sessions were led by a PEERS-certified psychologist and an assistant behavioral coach. Weekly meetings were held to align session content and address potential issues.
Results: The culturally adapted Persian -translated version of PEERS® was perceived as beneficial by young adults with ASD and their caregivers, improving social skills and quality of life. However, quantitative measures did not show significant changes, indicating a need for further refinement and investigation to achieve measurable improvements in social functioning.
Conclusions: While qualitative feedback indicates that both young adults with ASD and their caregivers found the caregiver-assisted social skills intervention to be beneficial in improving social skills and overall quality of life, the quantitative measures did not show significant changes. This suggests that while the intervention may have positive perceptual impacts, further refinement and investigation are needed to achieve measurable improvements in social functioning.

Persistent negative symptoms in young people at clinical high risk of psychosis: findings from an Italian longitudinal study.

L. Pelizza[1], C. Ricci[1], E. Leuci[2], E. Quattrone[2], M. Menchetti[1] and F. Catalano[3]*

[1]Department of Biomedical and Neuromotor Sciences, University of Bologna, Bologna; [2]Department of Mental Health, AUSL di Parma, Parma and [3]University of Bologna Italy, Bologna, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.410

Introduction: Negative symptoms in CHR-P people are generally not responsive to treatments and commonly related to poorer functional outcome. However, less research attention has been dedicated to Persistent Negative Symptoms (PNS), defined as clinically stable negative symptoms of moderate severity evident for at least 6 months.
Objectives: This study aims to (a) determine the prevalence of PNS in a sample of young people at CHR-P; (b) investigate any association of PNS with functioning and clinical features; (c) examine longitudinal course of PNS across 2 years of follow-up and changes in PNS severity levels with specialized treatments.
Methods: One Hundred Eighty CHR-P participants were recruited and were divided into CHR-P/PNS + and CHR-P/PNS− subgroups according to the presence/absence of PNS. The clinical assessments were based on the PANSS and the GAF and were conducted at baseline and every 12 months during the follow-up. Association of PNS with sociodemopgraphic, clinical, psychopathological and treatment variables were examined using linear regression analysis.
Results: Twenty four participants showed PNS at entry. Of them, 21 concluded the 2-year follow-up period. At baseline, the CHR-P/PNS + participants showed more educational and employment deficits, and more social and functioning impairment. During the follow-up, the CHR-P/PNS + subgroup had a significant longitudinal decrease in negative symptoms, which was specifically related to antidepressant treatment. CHR-P/PNS + subjects also showed a higher incidence of new hospitalization and a lower functional recovery over time.
Conclusions: Our findings support that the persistence of negative symptoms in CHR-P people is longitudinally related to worse daily functioning and more severe clinical conditions that are at higher risk of hospitalization and are less responsive to specialized treatments.

Theoretical Mechanisms of GLP-1 Receptor Agonist-Induced Depression in Obesity Treatment

A. Stewart[1]* and B. Carr[2]

[1]College of Allopathic Medicine, Nova Southeastern Univeristy, Ft. Lauderdale and [2]Psychiatry, University of Florida, Gainesville, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.411

Introduction: Recent post-marketing data reports an increased incidence of depression and suicidal ideation in patients using glucagon-like peptide-1 receptor agonists (GLP-1 RAs) for diabetes and obesity management compared to metformin. Despite ongoing FDA evaluations finding no causal link, various studies present mixed findings and propose several biologically plausible mechanisms for GLP-1 RA-induced depression. Increased depression rates observed post-bariatric surgery suggest similar outcomes following significant weight loss with GLP-1 RAs. This review explores these mechanisms to provide a comprehensive understanding and guide clinical practice.
Objectives: To evaluate theoretical mechanisms underlying GLP-1 RA-induced depression in patients undergoing obesity treatment and to offer insight for later clinical decision making.
Methods: A comprehensive literature review was conducted using PubMed and MEDLINE, alongside current FDA updates. The review focused on GLP-1 RA side effects related to depression and included case reports of depression in patients on GLP-1 RA therapy. Data on incidence and clinical management were synthesized to develop a cohesive understanding of associated risks and recommended practices.
Results: The review identified several theoretical mechanisms through which GLP-1 RAs may induce depression. Firstly, GLP-1 RAs may reduce food cravings by altering hedonic tone, potentially

diminishing pleasure from various activities. Secondly, rapid changes in gut microbiota may lead to gut-brain axis dysregulation, contributing to depressive symptoms. Thirdly, GLP-1 RAs have been linked to reduced absorption of vitamin B-12 and other essential nutrients, impacting brain function and mood. Social media data and individual case reports reveal mixed mental health outcomes, with some users reporting improved mood and others experiencing mood deterioration.

Conclusions: The evidence on GLP-1 RAs and depression is mixed. While some studies suggest negative mood effects, others, including the FDA's large-scale evaluations, have not established a causal link. Notably, semaglutide may be associated with a lower risk of suicidal thoughts. These findings emphasize the complexity of this issue and the necessity for ongoing monitoring and personalized patient care. Regular mental health screenings for patients on GLP-1 RAs, especially those with a history of depression, are recommended. Addressing potential nutrient deficiencies through dietary adjustments or supplements is crucial. Patients should be informed about potential mood changes and encouraged to report any adverse effects. Further research, particularly more longitudinal and large-scale studies, is needed to clarify the relationship between GLP-1 RAs and mental health outcomes.

Examining the Discontinuation of Clozapine Due to Serious Side Effects Over A Decade at a University Hospital Inpatient Clinic

D. Koçyiğit[1], R. Aktaş[1], S. Çoşkun[1], E. Özçelik Eroğlu[1], E. Mutlu[1] and A. E. Anıl Yağcıoğlu[1,*]

[1]Department of Psychiatry, Hacettepe University, Ankara, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.412

Introduction: Clozapine stands out among all other antipsychotics due to its superior efficacy in treatment resistant schizophrenia. Despite its proven superiority, it is not the first antipsyhotic choice on grounds of serious side effects. Clozapine remains underutilized, primarily due to its troubled safety profile.Lower prescription rates may be related with physicians' hesitation because of side effects rather than patients' unwillingness to use the drug.

Objectives: To elaborate on the life-threatening side effects and discontinuation of clozapine, we retrospectively reviewed the medical records of all patients admitted to the inpatient psychiatry unit at the Hospital of Hacettepe University Faculty of Medicine, Ankara, Türkiye between January 2010 and April 2022.

Methods: Hospital records of inpatients with psychotic disorders, identified by ICD-10 codes (F20.X, F25.X, F.22, F28, F29), and patients with bipolar affective disorder, identified by ICD-10 code (F31.X) who discontinued clozapine during their hospitalization due to serious side effects were thoroughly investigated.

Results: Among a total of 2298 patients hospitalized during the specified period, 178 patients with psychotic disorders and 21 patients with bipolar affective disorder were clozapine users. In this sample, 14 patients with psychotic and 3 patients with bipolar affective disorders had a serious side effect due to clozapine which led to discontinuation in 15 patients (7.53%). The median age of the cases was 32-years (min-max:18-62), the median duration of illness was 10-years (min-max:2-30), and the mean clozapine dose at onset of the serious side effect was 245±149.95 mg/day. The observed serious side effecs associated with clozapine included myocarditis (n=10, 58.8%), agranulocytosis (n=3, 17.6%), neutropenia (n= 1, % 5.88), pancreatitis and myocarditis (n=1, 5.88%), refractory increase in level of C-reactive protein (n=1, 5.88%), refractory constipation, weight gain and worsening in obsessive-compulsive symptoms (n=1, 5.88%), and suspicion of neurotoxicity of clozapine in a patient with mutation in multi-drug resistance-1 gene (n=1, 5.88%). There was no report of sudden death, cardiac arrest or need for intensive care unit. The majority of serious side effects (88.2%) occurred within the first 6 months of clozapine initiation. Two patients (11.7%) were able to continue clozapine with clinical management. Among patients who discontinued clozapine, 3 (20%) were rechallenged with clozapine in which 2 attempts (66,6%) were successful.

Conclusions: An examination of 12 years of inpatient clozapine treatment at a University Hospital clinic revealed that even life-threatening side effects of clozapine can be managed successfully with close clinical care. Physicians' concern about serious side effects should not lead to underutilization of clozapine in patients who could benefit from its trial.

Torsade de Pointes: How Much Do Psychotropics Really Contribute?

J. Brouillette[1,*], S. Cyr[1], C. Fiset[1], R. Tadros[1], L. Abdelaziz[1], A. Minichiello[1], M. Bouvier[1], S. Levesque[1], C. Daval[1], V. Lavigne[1], P. Khairy[1] and S. Nattel[1]

[1]Montreal Heart Institute, Montreal, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.413

Introduction: Based on potential risk of torsade de pointes (TdeP; a rare arrhythmia), regulatory agencies have issue warning for two specific antidepressants. This has translated in clinic as a class effect in that every antidepressant monography or guideline warns against this side effect. Current data suggest that excessive caution in the face of this undesirable effect could have a deleterious effect on mortality. Most research on antidepressant/antipsychotic drugs and TdeP is based on its intermediate marker, the corrected QT interval (QTc) on the electrocardiogram, or case reports.

Objectives: Our objective is to measure the contribution of psychotropic drugs (antidepressants and antipsychotics) to the arrhythmia itself, and measure its weight among all other risk factors.

Methods: We completed a retrospective case-control study at the Montreal Heart Institute, with a 1:3 ratio (n=440). We performed

hierarchical logistic regression for TdeP (cases vs controls), and included the following independent variables: sex, age, hypokalemia, acute myocardial infarction, left ventricular dysfunction, hepatic failure and/or renal failure, other QTc-prolonging drugs, and psychotropic drugs. We then calculated population attributable risks (PAR).

Results: In our final model which adjust risk factors for one another, women, acute myocardial infarction, hypokalemia, left ventricular dysfunction, QTc-prolonging drugs, and use of ≥2 antidepressants were significantly associated with TdeP. Age, hepatic and/or renal failure and antidepressants/antipsychotic drug monotherapy were not. The PAR for use of ≥2 antidepressants was 6.3%, while those of other QTc-prolonging drugs, female sex, and left ventricular dysfunction were 55.1%, 41.8%, and 25.6%, respectively.

Conclusions: When adjusting for concomitant risk factors, monotherapy with antidepressant or antipsychotic drugs is not associated with TdeP. On its side, the use of ≥2 antidepressants is associated with TdeP, with a PAR of lesser magnitude than sex, left ventricular dysfunction, and other QTc-prolonging drugs. This research provides a more nuanced perspective on the relationship between psychotropic drugs and the occurrence of this arrhythmia.

Detection of dissociative states in patients during the administration of Es-ketamine by monitoring with the Dissociative Experience Scale II (DES II) - Part I

C. Serritella[1]*, F. Ferraiuolo[1], M. Piccirillo[2], E. Lastrucci[3], A. Frasso[4], G. De Mattia[1], T. Salvati[5] and D. Riccio[6]

[1]Università degli studi di Napoli Federico II, Psichiatria; [2]Seconda Università degli Studi di Napoli (SUN), Psichiatra, psicoterapeuta Cognitivo-Costruttivista, Napoli; [3]Università degli studi di Potenza, Scienze biostatistiche, Potenza; [4]ASL Caserta, UOSM 12, Psicologa, Caserta; [5]Università degli studi Suor Orsola Benincasa, Professoressa, Psicoterapeuta, Napoli and [6]Università Telematica Pegaso, Linguista, Milano, Italy

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.414

Introduction: The effectiveness of Es-ketamine therapy in the treatment of psycho-pathological symptoms is the subject of growing interest in the scientific community. Through the use of validated psychometric instruments, this study aims to delineate more precisely the mechanisms of action and clinical potential of this therapy, contributing to the advancement of knowledge in psychiatry.

Objectives: The main objective of the present study is to analyses in depth and systematically the onset and development of the dissociative state, as well as the different forms of dissociation, in patients undergoing treatment with Es-ketamine (Spravato). Particular attention will be paid to the distinction between drug-induced dissociation and dissociation of a psychotic nature.

Methods: Two psychometric instruments were used: the Clinical Global Impression (CGI) and the Dissociative Experience Scale II (DES II). The CGI assessed symptom severity (Severity of Illness, SI), the overall clinical improvement (Global Improvement, GI) and treatment effectiveness with respect to side effects (Efficacy Index, EI). DES II measured the frequency and intensity of dissociative symptoms, considering a score of ≥30 as pathological. The initial sample of 16 patients was reduced to 15 (6 males and 9 females) due to the exclusion of one participant due to incomplete data.

Results: Preliminary results indicate that treatment with Es-ketamine led to significant clinical improvement in the majority of patients. Quantitative analysis showed an improvement between the initial (T0) and subsequent (T1) assessment on both scales used. In the DES II, a mean effect of +0.98 was found, with a cumulative reduction of 14.65 points, indicating a decrease in dissociative symptomatology. In the CGI, the mean improvement presented an effect size of +56.57, with a range from +30.4 to +117.9, suggesting significant variability in treatment response. In two patients, a 31-year-old man and a 19-year-old woman, a clinical worsening associated with high levels of dissociation was observed, highlighting the potential role of factors such as age and dissociative vulnerability in treatment response.

Conclusions: The CGI and DES II scales proved effective in monitoring clinical changes in patients treated with Es-ketamine, highlighting their complementarity. This study represents the first attempt to differentiate between traumatic and psychotic dissociation in Es-ketamine-treated patients, suggesting new opportunities to tailor therapeutic interventions therapeutic interventions. Further studies with larger samples and more robust methodological designs are needed to confirm the preliminary results, as well as to investigate the long-term impact of Esketamine on dissociation and the potential associated risks.

doi: 10.1192/j.eurpsy.2025.415

Introduction: Emerging research suggests that retinal structure, assessed via optical coherence tomography (OCT), may be a potential biomarker in Schizophrenia Spectrum Disorders (SSD). However, the relationship between retinal and cognitive parameters in the early stages of the disease remains underexplored.
Objectives: To examine the correlation between retinal structure and cognitive functioning in patients with early-course SSD.
Methods: A cross-sectional sample of 26 SSD cases and 25 age- and gender-matched healthy controls (HCs) underwent OCT imaging. Peripapillary retinal nerve fiber layer (pRNFL), macular, and ganglion cell-inner plexiform layer (GCL+IPL) thicknesses were measured. Cognitive domains, including verbal memory (California Verbal Learning Test, CVLT[Delis et al. 2000]), working memory (WAIS-III Letter–Number Sequencing Subtest[Wechsler 2011]), processing speed (Trail Making Test-A, TMT-A[Reitan et al.Clin Neuropsychol 1995;9:50-6]), sustained attention (Conners' Continuous Performance Test, CPT[Rosvold et al.J Consult Psychol 1956;20:343]), executive function (Wisconsin Card Sorting Test, WCST[Heaton 2008]), and social cognition (Mayer-Salovey-Caruso Emotional Intelligence Test, MSCEIT[Mayer et al.Emotion 2003;3:97-105]), were assessed and then transformed into t-scores. A Principal Component Analysis(PCA) was conducted, and associations between retinal and cognitive parameters were explored with Pearson/Spearman correlations; statistical significance was set at $p<0.05$.
Results: SSD patients (mean age:31.9years[SD=1.2]; males n=11 [44%]; mean duration of illness:32.5months[SD=22.3]) exhibited thicker pRNFL in both the right (t=-2.25,p=0.03) and left (t=-2.08,p=0.04) eyes compared to HCs (mean age:32.7years [SD=1.9]; males n=13[50%]). A thicker pRNFL was associated with a poorer cognitive performance: verbal (r=-0.53,p=0.04) and working memory (r=-0.64,p=0.01) was correlated with average pRNFL thickness; processing speed was associated with superior temporal pRNFL thickness (rs=-0.54,p=0.02); sustained attention was correlated with inferior nasal pRNFL thickness (rs=-0.54,p=0.04); social cognition was correlated with average pRNFL thickness (r=-0.72, p=0.03) and temporal pRNFL thickness (r=-0.82, p=0.01). Executive function was not associated with retinal measures, and macular and GCL+IPL thickness did not correlate significantly with cognitive variables.
Conclusions: Our findings suggest relationships between increased pRNFL thickness and impaired cognitive functioning in early-course SSD patients. Previous studies have reported that pRNFL might be thicker during the initial stages of SSD and thins as the disease progresses, highlighting the role of inflammatory processes in both retinal changes and cognitive impairment. Further longitudinal multimodal research is warranted to explore the utility of retinal imaging in monitoring cognitive outcomes in SSD.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.416

Introduction: Psychotic disorders are a major cause of global disability. While antipsychotic treatments are effective, their impact is limited. Metacognitive Training (MCT) reduces positive and negative symptoms, but neurocognitive deficits hinder therapy. Cognitive Rehabilitation (CR) may help improve these skills. Combining both therapies could offer better results, but studies are lacking to confirm whether there is any real improvement.
Objectives: Compare the efficacy of combined CR+MCT therapy vs. MCT alone in clinical and functional recovery in nonaffective psychotic disorders.
Methods: This ongoing randomized trial includes 85 patients (56.5% female, mean age 40.40±10.17), with 38 receiving CR +MCT and 47 receiving MCT only. Sociodemographic and clinical data (WHO-DAS-II, PANSS, GAF, and criteria for clinical remission and functional recovery) were collected pre-and post-treatment. Generalized linear models were used, with post-treatment scores as the dependent variable, baseline scores, and RC+MCT group as covariates.
Results: No significant differences were found between groups. However, CR+MCT showed a greater reduction in positive symptoms ($M_{\text{post-pre}}$ = -3) vs. MCT ($M_{\text{post-pre}}$ = -2.2) with no changes in negative symptoms. CR+MCT presented a higher percentage of clinical remission (12,1%) vs MCT (0%) post-treatment. Both groups improve in functional recovery, with greater results in MCT alone (10,9%$_{\text{CR+MCT}}$ vs 22,8%$_{\text{MCT}}$). CR+MCT also had greater reductions in functional disability ($M_{\text{post-pre}}$ = -3,4) vs. MCT alone ($M_{\text{post-pre}}$ = -2,2).
Conclusions: The group that has received the combined RC+MCT therapy has shown better results in clinical remission and functional recovery, the last in terms of disability, than the MCT-only group. The small sample size limits statistical significance.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.417

Introduction: Early Intervention in Psychosis (EIP) services have been youth-focused since their inception. Recently, NICE recommend the expansion of the age acceptability criterion to 65 years, from the previous cut-off of 35 years.
Objectives: The aim of this study is to compare the demographic and clinical characteristics between patients below and above 35 years of an epidemiological cohort of first-episode psychosis patients treated in the Early Intervention Service of Cantabria (ITPCan).
Methods: This is an study of the 207 consecutive patients aged from 17 to 65 who were admitted to the Service of University Hospital Marqués de Valdecilla, Spain, from January 2020 to July 2024. Descriptive statistics and between groups comparisons are reported.
Results: A large proportion (51.2%) of those who presented a first episode of psychosis did so after the age of 35. The over 35s were predominantly female (65,1%), whilst the under 35s were predominantly male (58.4%) ($\chi2$=11.495, P=0.01).
No significant differences were found between the age groups in terms of the need for psychiatric care in the different facilities (emergency care, day hospital, acute unit admission or mid-stay unit admission), nor in the presentation of autolytic attempts or the requirement for mechanical restraint.
DUP was significantly higher in the over 35s (u=4183.5, P=0.006), with a median of 4 months versus a median of 2 in the under 35s. As for the use of drugs, 36.6% of the under 35s regularly consume cannabis compared to 6.6% of the over 35s ($\chi2$=15.783, P=0), while there are no differences in the consumption of tobacco or alcohol. There was a higher proportion of patients over 35 with diabetes (4.7% vs. 0%, $\chi2$=4.407, P=0.036), hypercholesterolemia (20.8% vs. 4%; $\chi2$=11.750, P=0.001) and a history of cardiovascular disease (7.5% vs. 1%, $\chi2$=4.678, P=0.03), but no significant differences were observed between groups in the history of cerebrovascular disease or hypertension.
In reference to diagnosis, non-affective psychosis was more frequent in both groups (73.3% in under 35s and 90.6% in over 35s), with the diagnosis of delusional disorder being more frequent in the group over 35s (18.9% vs 1%, $\chi2$=16.127, P=0). On the other hand, the diagnosis of manic episode with psychotic symptoms was significantly higher in those under 35 years of age (22.8% vs 9.4%, $\chi2$=6.867, P=0.009).
Conclusions: Despite the high proportion of patients who have a late onset of psychosis, specially women, this remains an understudied group. EIP services focused on young people are gender and age inequitable. There are some clinical and demographic differences between the two age groups and EIP services should ensure that the treatments offered are tailored to the needs of both groups.

Long-Term Survival and Mortality in Schizophrenia: Insights from a 10-Year Follow-Up Study

A. V. Popa[1,2*], A. Teodorescu[1,2] and P. I. Ifteni[1,2]

[1]Faculty of Medicine, Transilvania University of Brașov and [2]Psychiatry, Clinical Hospital of Psychiatry and Neurology of Brașov, Brașov, Romania
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.418

Introduction: Schizophrenia is a severe mental disorder linked to a life expectancy 15-20 years shorter than the general population[1], due to higher rates of cardiovascular disease, cancer, metabolic disorders, and increased risk of suicide and accidental deaths[2].
Objectives: This study aims to analyze survival and causes of death in a cohort of schizophrenia patients over a 10-year period, providing insights into mortality patterns in this population.
Methods: This 10-year retrospective study followed 635 schizophrenia patients, aged 18 or older, enrolled from 2010 to 2013 at the Clinical Hospital of Psychiatry and Neurology, Brasov, Romania. Patients with schizo-affective or other psychotic disorders were excluded. Data included demographics, clinical history, and survival outcomes, with causes of death confirmed by a Forensic Medical Specialist.
Results: The study included 635 patients diagnosed with schizophrenia. The mean age at baseline was 48,01 ± 11.36, 42.04% were males, and the mean age of onset of schizophrenia was 26.68 ± 8.01.The average duration of illness was 21.27 ± 11.41 years. Among the cohort, 20.31% patients were treated with LAIs antipsychotics, and 17.16% were on clozapine. Of the 635 patients followed, 123 (19.4%) died during the 10-year follow-up. The average age at death was 59.04 ±11.96. According to the 2023 Eurohealth report and the World Health Organization, the overall life expectancy in Romania is 76.3 years [3]. The data on schizophrenia patients suggests a significant disparity between their average age at death and the overall life expectancy in Romania. Schizophrenia patients in Romania live, on average, about 17 years less than the general population. Of the deceased, 13% died in psychiatric wards, and 17.88% were in chronic care at the time. Among the deceased patients, 18 were on typical antipsychotic LAIs. None of the patients in the deceased cohort were on atypical LAIs. Cardiovascular disease was the leading cause of death (27.64%), followed by infections (17.07%) and cancer (12.19%). Metabolic causes accounted for 4.06%, respiratory for 1.62%, hepatic for 3.25%, and both neurological and gastrointestinal causes for 0.81%. The cause of death was undetermined in 15.45% of cases. Violent deaths accounted for 17.07% of cases, with 8 suicides and 13 accidents. Out of the 13 accidental deaths, 7 were due to choking-related asphyxiation during eating. Four of these patients were on haloperidol, 2 on quetiapine, and 1 on flupenthixol.
Conclusions: The 17-year lower life expectancy for schizophrenia patients highlights the urgent need for targeted public health interventions and improved preventive care. Additionally, the high mortality from cardiovascular disease, cancer, and infections, along with choking-related risks from antipsychotic medications, underscores the importance of careful medication management to enhance patient safety and survival.

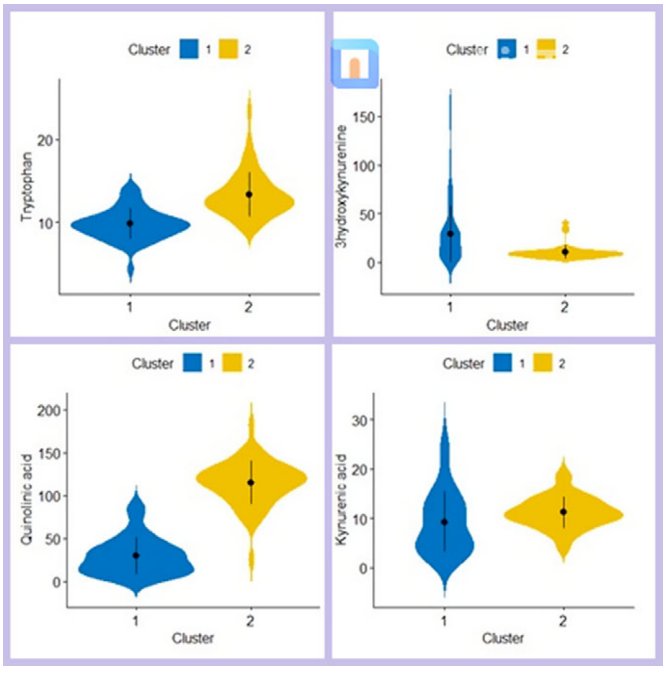
Disentangling the contribution of inflammatory markers and kynurenines to cognitive impairment in schizophrenia

J. Sapienza[1,2*], G. Agostoni[1], S. El Sagher[3], M. D'Incalci[4], M. Spangaro[1], M. Bechi[1], M. Buonocore[1], F. Cocchi[1], S. Comai[5], R. Cavallaro[3] and M. Bosia[3]

[1]Neurosciences, IRCSS San Raffaele, Milan; [2]Humanities and Life Sciences, IUSS, Pavia; [3]Vita-Salute San Raffaele University, Milan, Italy; [4]Neurosciences, Vita-Salute San Raffaele University, Milan and [5]Department of Pharmaceutical and Pharmacological Sciences, University of Padua, Padua, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.419

Introduction: Neuroinflammation and the Kynurenine Pathway (KP) have gained attention in the last decades in the pathogenesis of cognitive impairment in schizophrenia. Pro-inflammatory cytokines and microglia activation induce oxidative stress, neurodegeneration, white matter (WM) disruption and increased synaptic pruning and, importantly, activate the KP, whose metabolites have neurotoxic/neuroprotective and neuromodulatory properties on cholinergic and glutamatergic neurotransmission, two pivotal systems in cognitive processes.
Objectives: This study aims to investigate the relationship between levels of inflammatory markers and KP metabolites and cognition in schizophrenia with a focus on the differential impact of these biomarkers on the different phases of the illness.
Methods: Associations between levels of biomarkers and cognitive domains in the wholw sample of 120 patients with schizophrenia were firstly assessed. Then, patients were divided in two subsamples depending on the duration of illness, with the aim to evaluate the impact of inflammatory biomarkers and kynurenines on cognition depending on disease progression. Finally, we performed cluster analysis to investigate kynurenines as possible clustering variables with the final aim to attribute a different cognitive profile to each cluster.
Results: In the whole sample we found negative correlations between multiple inflammatory markers including IL-1β, IL-6, TNF-α, and cognitive functions, particularly verbal memory. Negative associations between verbal memory and TNF-a, IFNg and IL-5 were found in early-phase patients compared to late-phase patients, who showed a less strong associations. Interestingly, kynurenines showed significant associations with cognition in multiple areas regardless of the duration of illness. Regarding clustering, Cluster 1 included patients with lower levels of Tryptophan, Quinolinic Acid, and Kynurenic Acid, as well as higher levels of 3-hydroxykynurenine, compared to Cluster 2 (Fig. 1). Interestingly the two clusters showed different cognitive profiles. Verbal memory, psychomotor speed and attention significantly differed between the two clusters, with Cluster 1 showing the most impaired cognition in all these domains (Fig. 2).

Image 1:



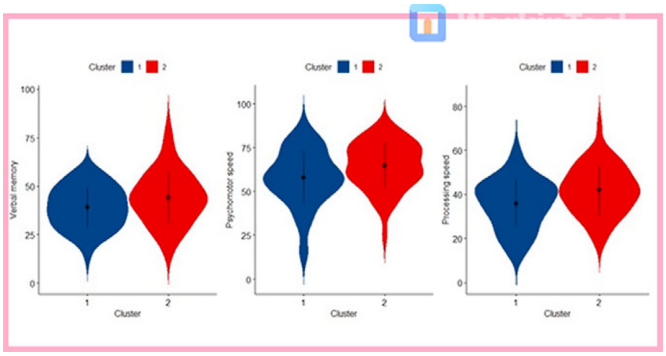


Image 2:

Conclusions: These results stress the primary importance of inflammation and KP abnormalities in cognitive impairment. The effects of inflammation on cognition seems to decline over time, while metabolites of the kynurenine pathway continue to have an impact. Probably, pro-inflammatory cytokines impact cognition more in patients with a shorter duration of illness as the biological bases of cognitive functions are more preserved (cortical volumes, synapses, WM integrity), whilw the neuromodulation of KP metabolites combined with their neurotoxic/neuroprotective profile can explain the diferential effect.

EPP066

Disentangling clinical heterogeneity in schizophrenia through neuropsychophysiological profiles

G. Agostoni[1]*, S. Zago[2], M. Bechi[3], J. Sapienza[3], R. Cavallaro[1], V. Bambini[4], G. Arcara[2] and M. Bosia[1]

[1]Vita-Salute San Raffaele University, Milan; [2]IRCCS San Camillo, Venezia; [3]IRCCS San Raffaele, Milan and [4]Istituto Universitario di Studi Superiori IUSS, Pavia, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.420

Introduction: Cognitive disruption is a key feature in schizophrenia, and the identification of the neurophysiological underpinnings is of particular interest. One of the most promising markers of cognition is aperiodic activity, which is considered as a proxy measure of excitation inhibition (E/I) balance, stemming from the equilibrium between glutamatergic and GABAergic neurotransmission. E/I alteration has been found in multiple disorders, but its relationship with cognition in schizophrenia has never been explored.
Objectives: This study aims at demonstrating the link between aperiodic activity and cognition in schizophrenia, and at creating neuropsychophysiological profiles, associated with clinical and functional features.
Methods: 48 patients with schizophrenia were assessed for cognition, well-being and the severity of psychopathology and underwent an electroencephalogram (EEG) recording during a resting state. EEG tracks were processed to extract aperiodic parameters (offset and exponent). Pearson correlation analyses between

aperiodic and cognitive measures were performed. Aperiodic indexes and the related cognitive domains were used to create neuropsychophysiological profiles, using a two-step cluster analysis. Analyses of Variance were performed to characterize significant differences in severity of psychopathology and well-being between profiles. Moderation analyses were run to identify the interplay between profiles, psychopathological severity and well-being.

Results: The mean aperiodic offset was -12.45 (± 0.65), while the mean exponent was 0.85 (± 0.28). Significant correlations with aperiodic parameters were found for: Working Memory, Processing Speed and Psychomotor Speed (Fig1-2). Cluster analysis identified two profiles (Profile1 N=15, Profile2 N=33): Profile1 had a higher offset, a steeper slope. ANOVAs revealed that Profile1 showed significantly higher scores in Working Memory and Processing speed, and lower levels of General Psychopathology, Anxiety/Depression and Uncontrolled Excitement and Hostility. Lastly, mediation models, showed an interaction between Profiles (R^2=0.21, p=.04) and Anxiety/Depression as well as between Profiles and General psychopathology (R^2=0.30, p=.003) on Self-Acceptance, with significant negative relationship only in Profile2 in both models (Fig 3).

Image 1:

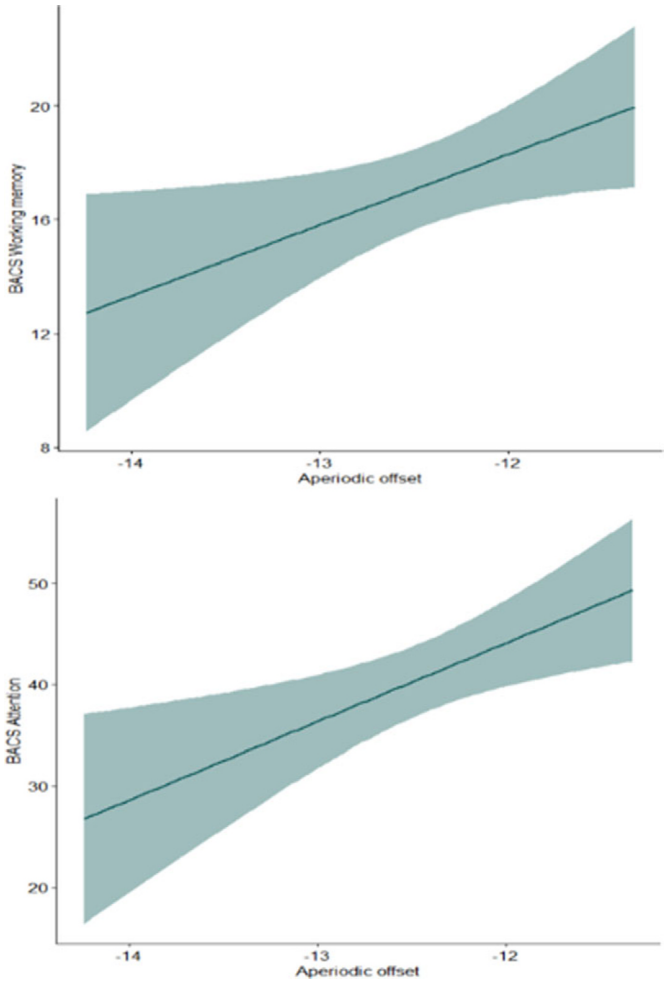

Image 2:

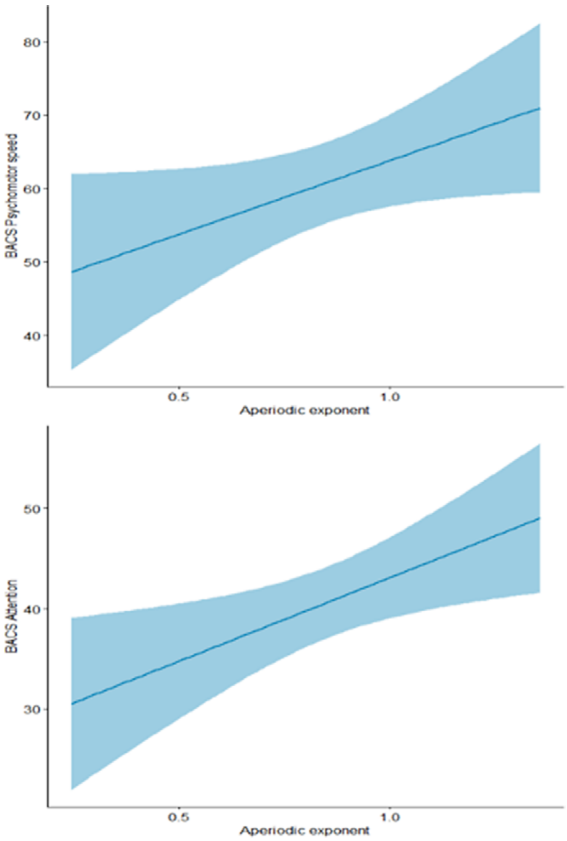

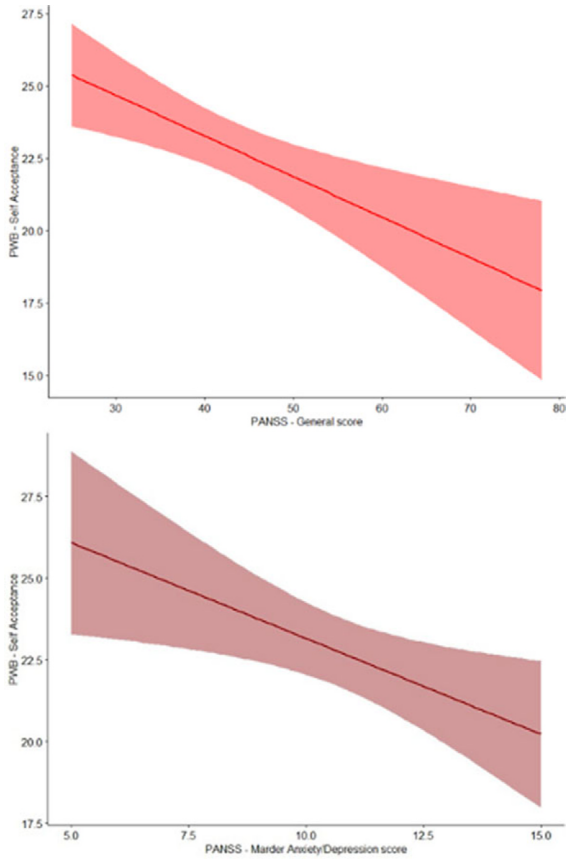

Image 3:

Conclusions: Our data support an altered E/I balance in schizophrenia and innovatively show a direct link between aperiodic activity and the cognitive disruption. This relationship is further confirmed by the identification of two profiles, characterized by distinct neuropsychological and neurophysiological measures, with a flatter aperiodic slope, corresponding to an altered E/I balance, being associated with more severe cognitive impairment and illness severity. The clinical relevance is highlighted by the interplay between symptoms severity and neuropsychophysiological patterns on subjective well-being.

The Influence of Birth Weight on Cognitive Reserve and its impact on one-year Functioning in First-Episode Psychosis patients

M. F. Forte[1]*, S. Amoretti[2], A. Sánchez-Torres[3], L. Pina-Camacho[4], E. Vieta[1] and C. García-Rizo[5]

[1]Bipolar Disorders Unit,Hospital Clinic,Institute of Neurosciences, UB, IDIBAPS, CIBERSAM, Barcelona, Spain; [2]Group of Psychiatry, Mental Health and Addictions,VHIR, CIBERSAM, Barcelona, Spain, Barcelona; [3]IdiSNA, Navarra Institute for Health Research, Pamplona, Spain, Pamplona; [4]Child and Adolescent Psychiatry Department, Hospital General Universitario Gregorio Marañón,Madrid, Spain, Madrid and [5]Barcelona Clinic Schizophrenia Unit,UB, IDIBAPS, CIBERSAM, Barcelona,Spain., Barcelona, Spain

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.421

Introduction: Cognition is key to long-term outcomes in first-episode psychosis (FEP). Obstetric complications affect working and verbal memory in schizophrenia (Amoretti *et al.* Psychol Med, 2022;52:2874-2884). Among them, birth weight (BW), an indicator of prenatal development, has been studied in relation to cognition (Krishna *et al.* Int J Geriatr Psychiatry, 2019;34:1139-1169). Higher cognitive reserve (CR) is associated with better cognitive and functional outcomes (Amoretti *et al.* Psychol Med, 2022;52:526-537). It is hypothesized that low BW impacts fetal brain development, reducing CR and later functioning (Krishna *et al.* Int Psychogeriatr, 2021;1-14)

Objectives: To examine the relationship between BW and functioning one year after the onset of psychosis, mediated by CR and cognitive performance

Methods: 117 FEP patients and 224 healthy controls (HC) were recruited. BW was collected as a continuous variable in grams. The Functioning Assessment Short Test (FAST) assessed functioning. CR was quantified via premorbid IQ, educational attainment, and lifetime participation in leisure and social activities. A complete neurocognitive assessment was performed. Correlational analyses explored relationships between BW, CR, and cognition in FEP and HC. Serial mediation analysis (PROCESS Model 6) examined indirect effects of BW on functioning through CR and cognition

Results: No significant differences were found in BW between patients and HC (p=0.719). HC had higher CR than patients (p<0.001) **(Figure 1)**. In patients, BW correlated with CR (r=0.20, p=0.027), though no correlation was found in HC (r=0.10, p=0.216) **(Figure 2)**. The mediation model confirmed that BW was associated with CR (β=0.01, p=0.015), CR was linked to verbal memory (β=2.21, p=0.001) and verbal memory with functioning (β=0.07, p=0.004). The direct and total indirect effects of BW on functioning were non-significant. Among the indirect paths, only the one involving CR and verbal memory was significant (95%CI [0.0001, 0.0016]) **(Figure 3)**.

Image 1:

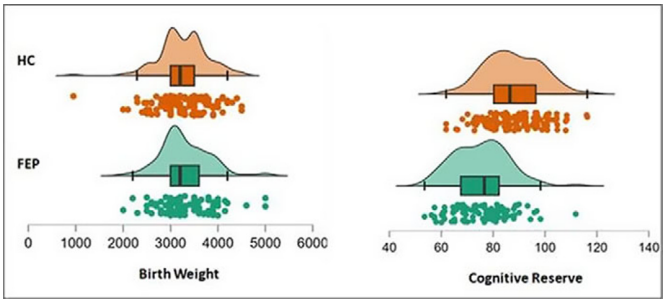

Image 2:

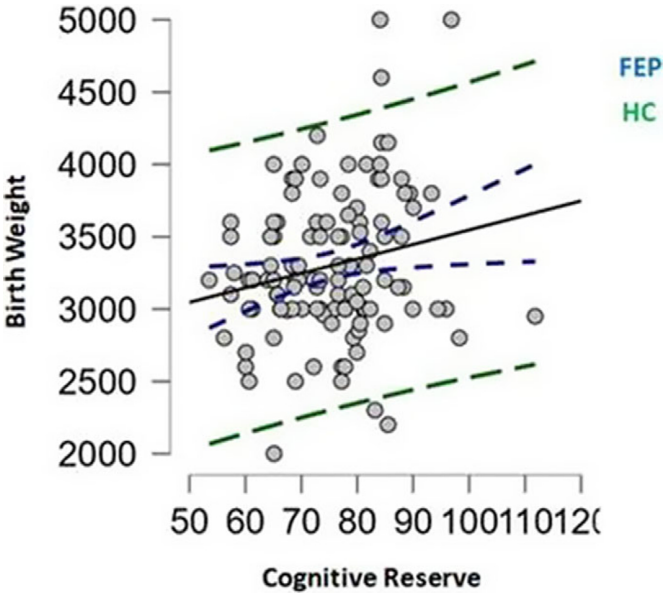

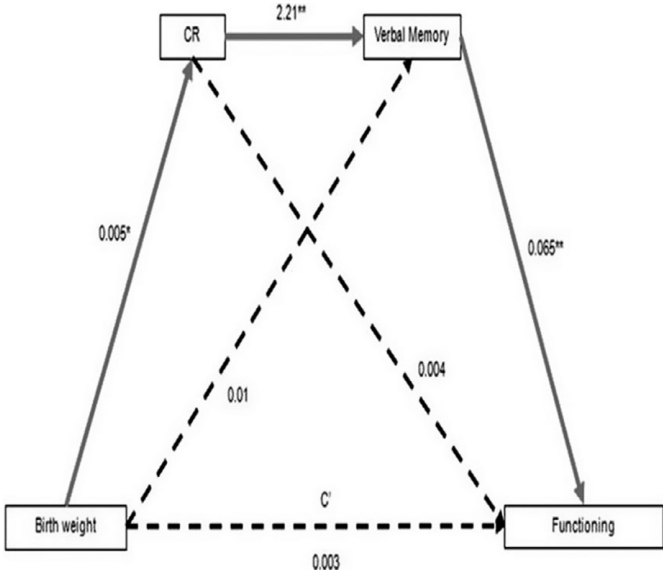

Image 3:

Conclusions: While BW did not have a direct impact on psychosocial functioning, it does influence CR, which in turn affects verbal memory.

Disclosure of Interest: None Declared

EPP069

CPAN: Validation of a novel transdiagnostic dimensional psychosis rating scale

L. Hermán[1]*, E. Vass[1] and J. M. Réthelyi[1]

[1]Department of Psychiatry and Psychotherapy, Semmelweis University, Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.422

Introduction: Psychiatric assessment of psychotic disorders has traditionally relied on categorical classification systems, but there is a shift towards a dimensional approach in DSM-5 and ICD-11. Schizophrenia is increasingly viewed as a spectrum disorder, with genetic studies indicating shared risk factors among schizophrenia, schizoaffective disorder, and bipolar disorder. However, there is currently no widely used transdiagnostic dimensional assessment tool in clinical practice. At Semmelweis University we have developed a scale which takes into account four major symptom groups (catatonia, affective-, positive and negative symptoms) and several important "specifiers" (disorganisation, bipolarity, prodromal symptoms, childhood onset, etc.). Clinicians should assess their patients with CPAN based on the long-term clinical presentation, contrary to PANSS and other cross-sectional tools, since our theory is that long-term traits represent underlying "biology" in a more precise manner than the rapidly changing status of patients, and therefore should show higher correlation with biomarkers like genetic and imaging data.
Objectives: We aimed to test the clinical usability of CPAN and its alignment with DSM-5 diagnostic categories and medication correlations in outpatient settings. Additionally, we planned a validation process to assess the tool's validity, interrater reliability, and test-retest reliability.
Methods: In our pilot study, six clinicians assessed 104 outpatient patients using CPAN, analyzing DSM-5 diagnoses and medications. Patients were clustered into four groups based on leading symptoms. In the validation study, 100 inpatients with severe psychotic symptoms will be assessed three times by two raters—one from the clinical team and one independent. We will compare CPAN's validity to PANSS results and assess test-retest reliability with three assessments.
Results: The pilot study demonstrated that CPAN is user-friendly, taking 1-2 minutes for familiar clinicians to complete. Four symptom clusters were identified: 1) schizophrenia with catatonic symptoms, 2) schizophrenia without catatonic symptoms, 3) schizoaffective disorder with negative symptoms, and 4) schizoaffective disorder without negative symptoms/bipolar disorder. Prescription patterns were correlated with symptom groups, but detailed analysis was limited due to the small sample size. Validation results are pending.
Conclusions: CPAN is a practical tool for assessing long-term symptom presentation in patients with psychotic disorders. Widespread use of this scale could provide valuable real-life data linking symptoms to medication use and clinical outcomes. The ongoing validation study will further establish the scale's validity and reliability

Validation of Ecological Sustained Attention Test for Schizophrenia

R. Komemi[1]*, T. Goldberger[1], A. Ariel[1], A. Zagory[1], M. Nahum[1] and L. Lipskaya-Velikovsky

[1]Hebrew University , Jerusalem, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.423

Introduction: Sustained attention deficit is a core feature of schizophrenia, however, its between-subjects and within-subject fluctuations are little understood. Moreover, although the pertinence of sustained attention for daily functioning has been widely discussed in the literature, research has not consistently demonstrated this association in schizophrenia. One possible reason is a use with non-ecological tasks for evaluation of SA, which may not fully capture real-world attentional demands. Indeed, existing tools demonstrate low ecological validity.
Objectives: This study aimed to develop daily-life task-based test of SA - Ecological Sustained Attention Task (Eco-SAT), and investigate its reliability and criterion, construct, and ecological validity in schizophrenia.
Methods: Eco-SAT was developed based on well-established CPT paradigm (320 trials presented for 500-3000ms, 12 min) simulating vacuum cleaning task. Twenty-one individuals with schizophrenia (age: M=42, SD=12.5; female: N=12, 57%) and 34 matched by age and gender healthy controls completed the Eco-SAT, non-ecological CPT, measures of cognition (MATRICS consensus cognitive battery: BACS, TMT, RBVMT & CFT), schizophrenia symptoms, and daily functioning using Observed Tasks of Daily Living test (OTDL, functional capacity) and Adults Subjective Assessment of Participation in daily life in an interchangeable order during one session.
Results: Eco-SAT demonstrated excellent test-retest reliability for Average RT (ICC = 0.84). Schizophrenia patients performed Eco-SAT significantly worse than controls on Average RT ($U=545$, $p < 0.01$), and variance RT ($U=518$, $p < 0.01$). Eco-SAT showed correlations with non-ecological SA task (all parameters; $0.45<r<0.75$, $p<.001$), MATRICS sub-tests of BACS (d prime, average RT, RT variance: $-0.54<r<0.3$, $p<.5$), TMT-B (average RT: $r=0.3$, $p<.05$), RBVMT (average RT, RT variance: $-0.5<r<-0.4$, $p<.01$), and CFT (average RT, RT variance:$-0.35<r<-0.34$, $p<.001$), positive schizophrenia symptoms (hit rate: $r=0.3$, $p<.05$) and the OTDL (RT variance, d prime, hit rate: $-0.35<r<0.3$,$p < .05$).
Conclusions: The study provides initial evidence of the psychometric properties of the Eco-SAT, an ecological measure of sustained attention in schizophrenia. Criterion validity was established for all Eco-SAT indices, while reliability, construct validity, and ecological validity were demonstrated for specific indices. The results suggest that average RT and RT variance are the most trustworthy indices. Although further research is required, these findings indicate that this ecological measure may offer a more

accurate way to assess attentional deficits in real-world activities, enhancing our understanding of attentional mechanisms in schizophrenia for both research and clinical applications.

Sexual Dysfunction and Self Esteem Among Tunisian Women

N. H. Benhamed[1]*, A. Hakiri[2], Y. Yaich[2] and B. Amamou[1]

[1]psychiatry department , EPS Fatouma Bourguiba , Monastir and [2]Psychiary B , Razi Hospital , Manouba, Tunisia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.424

Introduction: Sexual dysfunction is a multifaced issue that significantly affects women's physical and psychological health, contributing to broader emotional challenges such as dissatisfaction and inadequacy. In Tunisia, cultural and social factors, including gender roles and societal expectations, further shape women's perceptions and experiences of their sexual well-being. Self-esteem, a core component of psychological health, plays a crucial role in how women view and experience their sexuality, with lower self-esteem often intensifying sexual dysfunction.
Objectives: This study aims to explore the relationship between sexual dysfunction and self-esteem among Tunisian women within this cultural context.
Methods: a cross-sectional study was conducted online using a Google Forms questionnaire between July and August 2024.The inclusion criteria were sexually active women aged 18 years or older who provided informed consent to participate. Participants completed a self-administered questionnaire that included sociodemographic information, personal medical history, lifestyle habits, and psychometric assessments.
The Female Sexual Function Index (FSFI) was used to evaluate sexual function and self-esteem was assessed using the Rosenberg Self-Esteem Scale (RSE).
Results: A total of 180 women participated in the study. The average age of the sample was 32.79, with ages ranging from 21 to 60 years. In our study, 97.78% of the women were from urban areas 94.44% had a university degree 80% were employed and 62.78% were married. Regarding medical history , 21.11% reported organic issues , while 27.22% had a psychiatric history.
Lifestyle habits indicated that 18.9% of women smoked, and 21.1% consumed alcohol, while only 1.1% reported using psychoactive substances. . The majority, 93.89%, had a single partner, and 93.89% identified as heterosexual.
The evaluation of sexual function using the Female Sexual Function Index (FSFI) showed an average score of 23.37 ± 9.64, with 43.33% of participants experiencing sexual dysfunction. Specifically, 75.6% had issues with sexual desire, 83.3% reported pain during intercourse, and 71.7% experienced problems with sexual arousal.
The average self-esteem score, was 32.25 ± 5.75. A significant correlation was found between sexual dysfunction and self-esteem ($p < 10^{-3}$). Among the women with very low self-esteem, 80% experienced sexual dysfunction, while only 20% of those with very high self-esteem reported dysfunction.
Conclusions: Addressing both sexual health and self-esteem is essential for improving the emotional and psychological well-being of women in Tunisia. These findings underscore the importance of comprehensive sexual health interventions that promote positive self-esteem, ultimately enhancing the overall quality of life and fostering psychological resilience among Tunisian women.

Anxiety, depression, and negative affect in women with and without fertility issues: a network comparison study

N. Ćirović[1]*, J. Opsenica Kostić[1], M. Mitrović[1], M. Guberinić[1], M. Spasić Šnele[1], I. Janković[1] and M. Trenkić[2]

[1]Department of Psychology, Faculty of Philosophy, University of Niš and [2]Department of Gynecology and Obstetrics, Faculty of Medicine, University of Niš, Niš, Serbia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.425

Introduction: Infertility is a biopsychosocial crisis. While there are studies demonstrating heightened negative affect (e.g., depression and anxiety) in women undergoing in vitro Fertilization (IVF), the findings are still inconsistent. The network paradigm allows for a more in-depth examination of symptom dynamics behind specific psychopathological states. A recent development allows one to compare networks from different groups using three characteristics: global strength (overall level of network node connectivity), edge strength (level of association between symptoms), and network structure (comparing all edges in the network across two groups).
Objectives: This study aims to compare the networks of anxiety, depression, and negative affect across women who have fertility issues or undergoing IVF and women without these issues.
Methods: Sample 1 consisted of 197 women with fertility issues (age: M = 37.73, SD =5.13) and 370 women without such issues (age: M = 36.25, SD = 6). Sample 2 consisted of 205 women undergoing IVF (M = 40; SD = 5.29) and 222 mothers without fertility issues (M=28; SD = 4. 93). Sample 3 consisted of 162 women undergoing IVF (M= 35.58; SD=5.04) and 129 mothers without fertility issues (M= 34.37; SD= 4.94). PHQ-9 (Patient Health Questionnaire; depression measure) was administered to the sample 1, GAD (generalized anxiety disorder measure) was administered to sample 2, and PANAS - NA (negative affect measure) was administered to sample 3. NetworkComparisonTest R package was used to compare the networks. EBICglasso was used to estimate the networks.
Results: Regarding the depression symptoms (sample 1; image 1) - the networks across the two groups are highly similar with respect to overall connectivity (S =.051; p = .73) and overall network structure (M = .16, p =.87). Regarding generalized anxiety symptoms (sample 2; image 2), the findings are replicated with overall connectivity being the same across the two groups (S =.10, p = .34) and network structure being the same across the two groups (M = .28, p= .09). Finally, the negative affect (sample 3; image 3)

network connectivity (S = .02, p = .93) and network structure (M = .23, p = .53) are identical across the two groups.

Image 1:

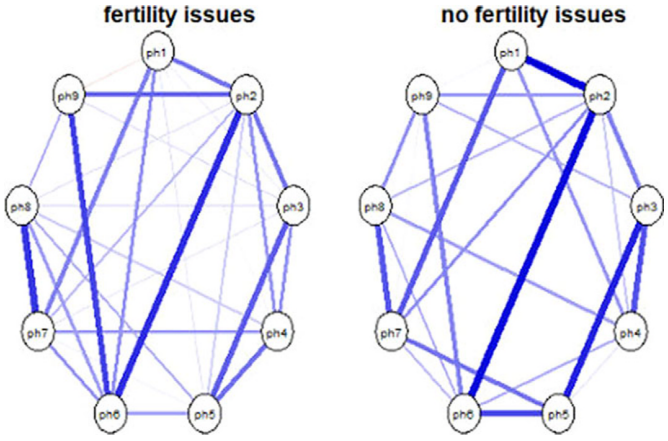

Image 2:

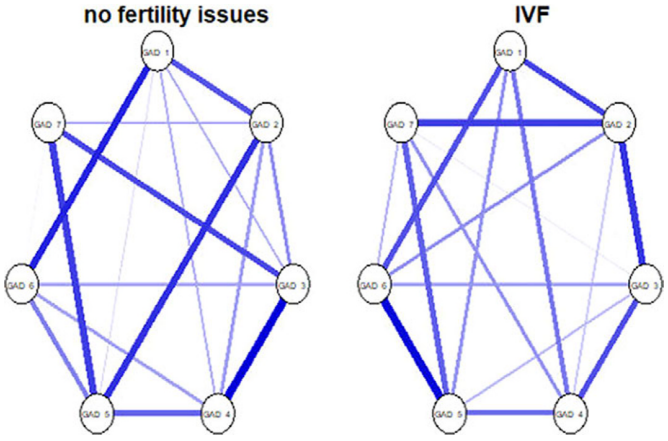

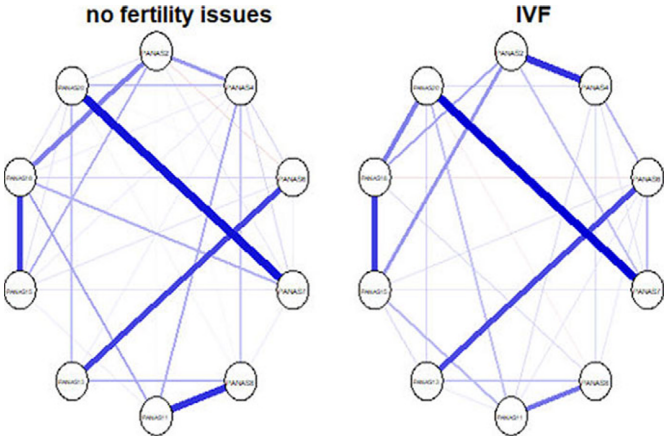

Image 3:

Conclusions: The networks of negative affect, depression, and anxiety are highly similar across women with fertility issues and women without such issues. Therefore, fertility issues do not seem to affect the structure of symptoms of depression, anxiety, and negative affect. Finally, it is argued here that the knowledge of these disorders (and negative affect) can be generalized to the population of women who have fertility issues.

Sex differences in adults with ADHD: A population based study

F. M. Ferrés[1]*, C. F. Grau[1], S. A. Guadall[1], V. R. Fernández[1], M. C. De La Cruz[1] and J. A. R. Quiroga[1]

[1]Psychiatry, Vall d'Hebron, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.426

Introduction: Attention-deficit/hyperactivity disorder (ADHD) is a common neurodevelopmental disorder that often persists into adulthood, significantly impacting daily functioning and quality of life. Studying sex differences in ADHD is crucial as females are frequently underdiagnosed or misdiagnosed, which can delay treatment and worsen outcomes. ADHD presents in three main subtypes: inattentive, hyperactive-impulsive, and combined. The combined subtype tends to cause more significant impairments, particularly in academic and social contexts. Males are more likely to be diagnosed with hyperactive-impulsive or combined types, while females often present with the inattentive subtype. A subtype-specific approach is essential, as it guides targeted interventions to address distinct behavioral and cognitive challenges, enhancing treatment efficacy and outcomes.

Objectives: This study aims to analyze differences in ADHD severity, comorbidity with other conditions, and socio-functional impact by ADHD subtype and sex, as well as to evaluate interactions between these variables.
Methods: This population-based study included 900 adults diagnosed with ADHD from a specialized ADHD clinic. Participants were classified by ADHD subtype and sex. Diagnostic and severity assessments were conducted using validated tools, including the CAADID-I, DIVA-5, ADHD Rating Scale (ADHD-RS), Wender Utah Rating Scale (WURS), and Clinical Global Impression Severity Scale (CGI-S). Comorbid psychiatric conditions and psychosocial functioning were evaluated using the BDI-II, STAI, BIS-11, PSQI, FAST, and WHODAS scales. Statistical analyses included bivariate, multivariate, and General Linear Model (GLM) methods.
Results: Females were diagnosed with ADHD later than males ($p=0.001$) and exhibited greater severity (ADHD-RS, $p<0.001$) and higher levels of depression and anxiety. No significant sex differences were observed in impulsivity or sleep quality. The combined ADHD subtype was associated with greater clinical severity and functional impairment. An interaction effect was found between sex and ADHD subtype only for WHODAS scores, with females in the combined subtype showing greater impairment.
Conclusions: ADHD presents differently across sexes and subtypes, with specific interactions observed in functional impairment. These findings emphasize the importance of considering sex and ADHD subtype independently to enhance diagnostic accuracy and inform targeted treatment strategies.

Prevalence and clinical correlates of intimate partner violence (IPV) among women with mental illness

A. Jeyagurunathan[1]*, E. Abdin[1], M. I. M. K. Shah[1], Y. T. Lee[1], V. D. Sagayadevan[1], S. Shafie[1], R. Sambasivam[1], Z. Yunjue[1], K. Xinyi[1], L. M. F. Eng[1], T. C. C. Ting[2], S. Basu[2], N. Chandwani[3], S. Y. L. Lee[3], J. Liu[1], S. A. Chong[1] and M. Subramaniam[1]

[1]Research Division; [2]Department of Psychosis and [3]Department of Mood and Anxiety, Institute of Mental Health, Singapore, Singapore
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.427

Introduction: Intimate partner violence (IPV) is a major public health concern. One of the most common forms of interpersonal violence concerns IPV, one in three women which is approximately 35% of women who experience physical and sexual violence by an intimate partner at some points in their lives. Women with mental illness are a vulnerable risk group for IPV.
Objectives: The current study aimed to assess the prevalence and clinical correlates of IPV among women outpatients with mental illness in a tertiary care psychiatric hospital.
Methods: 118 participants with a primary diagnosis of schizophrenia spectrum disorders or depression were recruited. Data on intimate partner violence (IPV) were assessed on the World Health Organization Violence Against Women (WHOVAW) scale, consisting of three domains-psychological, physical and sexual intimate partner violence. Psychopathology was measured using Brief Psychiatric Rating Scale-18 items (BPRS) questionnaire, consisting of five domains- positive symptoms, negative symptoms, resistance symptoms, activation symptoms, and affect symptoms. Data on socio-demographic characteristics were also obtained. Multivariable logistic regression was used for analysis.
Results: The mean (SD) age of women participants was 32.63 years (10.96). The overall prevalence of IPV among women with mental illness was 55.1%. Participants who were separated/widowed/divorced (versus single) were significantly more likely to experience total VAW scores (OR=14.57), and psychological (OR=21.64), and physical (OR=11.30) domains. Those who belong to Malay ethnicity (versus Chinese ethnicity) were significantly more likely to experience sexual abuse (OR=6.25). Women who were unemployed (versus employed) were significantly more likely to experience sexual IPV (OR=3.94). Women who experienced IPV (OR=1.36), psychological abuse (OR=1.30) and physical abuse (OR=1.25) were significantly more likely to have positive symptoms compared to those who did not experience IPV. Women who experienced IPV (OR=1.14) and psychological abuse (OR=1.13) were significantly more likely to have affect symptoms compared to those who did not experience IPV.
Conclusions: The study highlights the prevalence of IPV among women with mental illness. Overall VAW scores, psychological and physical IPV were strongly associated with higher score on the positive and affect symptoms on psychopathology scale. The high prevalence of IPV among this group of patients is concerning and mental health professionals should actively identify IPV and implement holistic interventions to ensure good care of women with mental illness.

EPP075

Gender Bias in ADHD Assessment: Are Male Partners Underestimating Female Symptoms on CAARS?

L. Moody[1]* and W. Mohamed[1]

[1]Mental Health and Wellbeing Services, Shrewsbury, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.428

Introduction: Social support can significantly influence mental health help-seeking (Rickwood et al., 2005). At MHWS, many patients are older and receiving late diagnoses for ADHD, often after experiencing lifelong difficulties. Research shows that women's mental health issues are frequently overlooked due to gender biases in healthcare (Kuehner, 2017), with men often underestimating the severity of their partners' mental health challenges (O'Neil, 2008; Cummings & Davies, 2002). This study explores whether similar patterns of underrepresentation occur in ADHD diagnoses, particularly in relation to observer gender and relationship to the patient.
Objectives: The study aimed to explore differences in ADHD assessment scores between patients and their observers based on the observer's gender and relationship to the patient. Additionally, it sought to determine whether the underrepresentation of ADHD symptoms differs based on these variables.
Methods: A cross-sectional comparative study was conducted involving 196 patients (123 females, 73 males) and their observers (135 females, 61 males) using the Conners' Adult ADHD Rating Scales (CAARS). The DSM-IV ADHD Symptoms Total was analyzed by comparing scores between patients and observers. The significance

level was set at 0.10 for exploratory purposes. Statistical analyses included the Mann-Whitney U test and Kruskal-Wallis test to explore the effects of observer gender and relationship on the discrepancy in ADHD symptom reporting.

Results:

1. Gender of the patient did not influence self-reported ADHD scores (*U = 5057.500, p = 0.705)*, but observer gender significantly impacted their rating of the patient's symptoms (*U = 5312.500, p = 0.032).*
2. Female patients' ADHD symptoms were underrepresented more than male patients' (U = 3941.500, p = 0.019).
3. Male observers underreported symptoms more than female observers (U = 4772.500, p = 0.075).
4. Observer relationship to the patient did not significantly affect ADHD symptom score discrepancies (H(3) = 4.928, p = 0.177).
5. Female partners were less likely to underrepresent ADHD symptoms compared to female parents, female and male family members, and male partners *(p = 0.028, 0.002, <0.001).*

Conclusions: Female patients were more likely to have their ADHD symptoms underrepresented, particularly by male observers and male partners, indicating potential gender biases in perception. The findings suggest that clinicians should be cautious of possible underreporting of ADHD symptoms by male observers and particularly male partners. Future research should explore whether hyperactivity or inattentiveness is more frequently underrepresented and further validate these exploratory findings.

Increased risk of alcohol use disorder following bariatric surgery: literature review

P. Alves Peixoto[1]* and A. F. Teixeira[2]

[1]Departamento de Psiquiatria e Saúde Mental, Unidade Local de Saúde do Tâmega e Sousa, Penafiel and [2]Centro de Respostas Integradas de Braga – Equipa de Tratamento de Guimarães, Instituto para os Comportamentos Aditivos e as Dependências , Guimarães, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.429

Introduction: In the last 50 years, obesity has become a leading cause of morbidity and decreased life expectancy, being associated with the development of cardiovascular disease, decreased mental health and overall decreased quality of life. The development of bariatric surgery as a treatment strategy in those in which attempts at conservative treatment yielded no satisfactory results has revolutionized treatment of refractory obesity. While short term gains in cardiovascular health are undeniable, long-term impact remains uncertain. More recently, there is emerging evidence of bariatric surgery being associated with *de novo* alcohol use disorder.

Objectives: We aimed to study the possible correlation between bariatric surgery and alcohol use disorder, specifically the individual risk factors that may promote such outcome. Moreover, we aimed to evaluate which surgical procedures are more eliciting of alcohol use disorder.

Methods: We performed a literature review using the database MEDLINE and obtained 241 results using the query terms "*bariatric surgery*" and "*alcohol*". Of these, we read all the summaries and subsequently selected 51 different scientific articles which we afterwards read in full. We then performed a literature review aiming to understand the maladaptive alcohol consumption patterns following bariatric surgery

Results: Most studies report maladaptive alcohol use following bariatric surgery. Outstandingly, this consumption pattern develops only at later follow up stages, usually over 3 years after surgery. Furthermore, not all types of bariatric surgery appear to pose the same iatrogenic risk. Gastric bypass poses the highest risk of new onset alcohol misuse, in comparison to sleeve gastrectomy or gastric band surgery. It is not yet fully understood the mechanism behind this pattern of alcohol misuse following surgery, but common reasons have been identified, including different social interaction patterns, addiction transfer, ambivalence towards bodily changes, increased mental vulnerability and different body response to the effects of alcohol.

Conclusions: The screening of alcohol misuse before and after bariatric surgery is of paramount importance to decrease the surgical iatrogenic risk and improve outcomes. Further research should be developed in understanding what are the risk factors and mechanistic pathways for alcohol misuse following bariatric surgery. Also, it should be investigated whether the treatment of alcohol misuse disorder differs between patients submitted to bariatric surgery or not.

Screening abstinent bariatric surgery patients for Behavioural Addictions using MMPI-2 data

F. Császár[1]*, R. Jávor[2] and I. B. Bálint[3]

[1]Psychiatry, Vas County Markusovszky University Teaching Hospital, Szombathely; [2]Faculty of Humanities and Social Sciences, University of Pécs, Pécs and [3]Department of Urology, Kanizsai Dorottya Hospital, Nagykanizsa, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.430

Introduction: Eating disorders comprise various conditions yet do not cover chronic overeating that may result in extreme obesity. Binge eating disorder with chronic somatic effects is not included in DSM-V; behavioural addictions do not comprise chronic overeating either. Neither do impulse control disorders. There are no actual screening tools for chronic overeating, and research is scarce on its chronic psychological effects

Objectives: This research aims to find the distinctive psychometric characteristics of addiction using MMPI-2 data taken from patients who underwent gastric surgery due to high-risk obesity or moderate-risk obesity with alarming comorbidities.

Methods: This study employed a consecutive patient cohort to evaluate complication rates and the efficacy of Single-Anastomosis duodeno-ileal bypass with Gastric plication (SADI-GP). Patient recruitment commenced in October 2018 and ceased in June 2019. The process involved preoperative assessment, surgery, and several postoperative follow-up appointments at 1, 3, 6, and 12 months. The Minnesota Multiphasic Personality Inventory

(MMPI-2) was administered during the 12-month follow-up. Participants aged between 18 and 65 years were included in the study, with body mass indexes (BMIs) exceeding 40 for individuals without comorbidities related to morbid obesity, and exceeding 35 for those with comorbidities related to morbid obesity, particularly related to glucose metabolism.
MMPI-2 scales previously confirmed to be related to SUD were analyzed, and common psychological comorbidities of SUD were searched for using these scales
Results: High scores on MAC-R, AAS, and APS scales are well-represented in the sample (Table 1).
The sample includes a high number of high scorers on Rc4 and a moderately high number of high scorers on Rc9 (Table 2).
Elevated individual scale scores form dual or triplet peak settings in the MMPI-2 results and may describe certain conditions, like SUD. The majority of the subjects showed SUD-like personality settings (Figure 1). This study is constrained by limitations about sample size, a dropout rate exceeding expectations, stringent exclusion criteria, male-to-female ratio, short-term results, and the absence of longitudinal data on psychological characteristics.

Image 1:

Table 1. **Frequencies along the Supplemental Scales**

	No. of patients with high score	%
Anxiety (A)	5	31,25%
Repression (R)	5	31,25%
Ego Strength (Es)	1	6,25%
Dominance (Do)	2	12,5%
Social Responsibility (Re)	3	18,75%
College Maladjustment (Mt)	5	31,25%
Post-Traumatic Stress Disorder Scale (Pk)	6	37,5%
Hostility (Ho)	6	37,5%
Over Controlled Hostility (O-H)	3	18,75%
MacAndrews Alcoholism Scale Revised (MAC-R)	9	56,25%
Addictions Acknowledgement Scale (AAS)	4	25%
Addiction Potential Scale (APS)	6	37,5%
Gender Role - Masculine Scale (GM)	3	18,75%
Gender Role - Feminine Scale (GF)	6	37,5%

Image 2:

Table 2. **Frequencies along the Revised Clinical Scales (Rc)**

	High score	%	Low score	%
Demoralization (Rcd)	4	25%	0	0
Somatic Complaints (Rc1)	2	12,5%	0	0
Low Positive Emotions (Rc2)	7	43,75%	0	0
High/Low scores on Cynicism (Rc3)	5	31,25%	3	18,75%
Antisocial Behavior (Rc4)	7	43,75%	0	0
Ideas of Persecution (Rc6)	2	12,5%	0	0
Dysfunctional Negative Emotions (Rc7)	4	25%	0	0
Aberrant Experiences (Rc8)	1	6,25%	0	0
Hypomanic Activation (Rc9)	4	25%	0	0

Image 3:

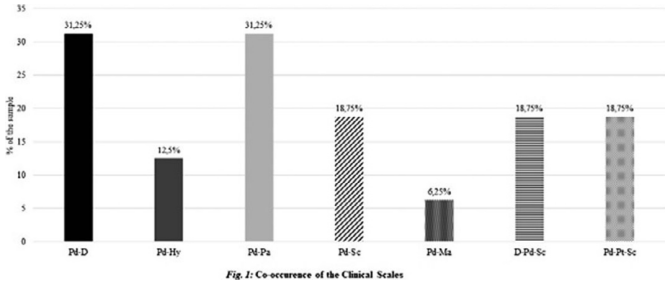

Fig. 1: **Co-occurence of the Clinical Scales**

Conclusions: We found the MacAndrews Revised (MAC-R) scale strong, with AAS and APS as intermediate indicators for non-substance-based behavioural addiction in our sample (Table 1). RC4 also seems to be a strong indicator (Table 2), along with Pd-D and Pd-Pa peaks (Figure 1).

Baclofen-Assisted Alcohol Detoxification with Minimal Diazepam Dosing: A Controlled Study at Corfu General Hospital Detoxification Unit

M. Demetriou[1]*, P. Argitis[1], V. Anagnostopoulou[1], M. Peyioti[2], F. Mourka[1], V. Markatis[1] and Z. Chaviaras[1]

[1]Psychiatry Department, General Hospital of Corfu, Corfu and [2]University General Hospital of Alexandroupolis, Alexandroupolis, Greece
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.431

Introduction: Alcohol withdrawal syndrome is a significant challenge in the management of alcohol use disorder, with traditional treatments often relying heavily on benzodiazepines like diazepam. This study aimed to explore the efficacy and safety of incorporating baclofen (30 mg/day) alongside minimal, tailored diazepam doses—adjusted according to alcohol intake and CIWA-Ar scores—to manage withdrawal symptoms more effectively than conventional diazepam protocols. By reducing the total diazepam needed and shortening detoxification time, the study highlights the potential of baclofen to offer a faster, safer approach to alcohol withdrawal treatment.
Objectives: To evaluate the efficacy and safety of combining baclofen (30 mg/day) with minimal diazepam doses—calculated based on alcohol consumption and adjusted by CIWA-Ar scores—in managing alcohol withdrawal symptoms more rapidly than standard diazepam protocols.
Methods: Sixty-nine patients with alcohol use disorder were enrolled and randomized into two groups. The baclofen group (n = 32) received baclofen 30 mg/day plus minimal diazepam, with initial diazepam doses based on average daily alcohol units consumed (1 mg diazepam per unit) and adjusted using CIWA-Ar scores. The standard group (n = 37) received a conventional diazepam-based detoxification regimen with fixed starting doses adjusted by withdrawal symptoms. Primary outcomes were the total diazepam dosage required and the duration of detoxification. Secondary outcomes included daily CIWA-Ar scores and incidence of adverse effects. Statistical analyses employed independent t-tests and chi-square tests, with $p < 0.05$ considered significant.
Results: The baclofen group required significantly less diazepam compared to the standard group (mean total dose: 30 ± 10 mg vs. 50 ± 15 mg; $p < 0.001$). They also experienced a shorter detoxification duration (mean: 15 ± 1 days vs. 19 ± 1 days; $p = 0.01$), indicating a faster withdrawal process. CIWA-Ar scores were consistently lower in the baclofen group throughout detoxification (mean: 6 ± 2 vs. 10 ± 3; $p < 0.001$), reflecting milder withdrawal symptoms. No significant adverse effects were observed in either group, including over-sedation, respiratory depression, or hallucinations.

Conclusions: Combining baclofen (30 mg/day) with minimal diazepam—calculated based on alcohol consumption and adjusted by CIWA-Ar scores—effectively controlled alcohol withdrawal, reduced diazepam use by 40%, and shortened detoxification by about four days. The protocol was well-tolerated and may benefit patients at risk from high benzodiazepine doses or in settings aiming to limit benzodiazepine use. These findings suggest baclofen can reduce medication needs and speed up recovery. Larger trials are needed to confirm these results and evaluate long-term outcomes like relapse rates and sustained abstinence.

Introduction: Quitting alcohol use has been described as the main factor capable of modifying the prognosis of alcohol-related liver disease (ArLD). However, retention to the addiction treatment in these patients is low, and relapse in alcohol use is common. Misconceptions in the patients knowledge of the disease and the treatment impact retention. To improve retention, we have designed a blended intervention consisting in a presential brief intervention combined with a gamified webapp (MyWayUp). The intervention provides information regarding the liver disease and treatment, how to improve the prognosis, healthy lifestyles and how to achieve behavioural changes. The intervention was designed using a co-creation approach, and is based in well-stablished psychological principles (cognitive behavioural therapy, CBT; motivational interviewing, MI; psychoeducation; game-based learning).
Objectives: The main objective is to explore the efficacy of the MyWayUp for improving retention to the addiction treatment in patients with ArLD at six months follow-up. As secondary objectives we explore: retention at 1 and three months, adherence to the treatment (attended visits from the total programmed), patterns of alcohol use and quality of life.
Methods: Prospective, randomised controlled trial, 6 months. Patients with ArLD onset would be invited to participate. If signed the informed consent, they would be randomised to the experimental or control condition. The experimental group would receive the brief intervention and given access to the webapp with a unique access code. Patients in the control group received treatment as usual, and after six months, if they had not adhered to the addiction unit, they would be invited to participate as experimental group. Both groups would be programmed the first visit with a psychiatrist, and followed at months 1, 3 and six after inclusion. The study was blinded for professionals and patients, and only one member in the research team would know the allocation group of each patient.
At baseline, sociodemographical variables were collected, as well as clinical data (presence of comorbidities), pattern of alcohol or other substances use (AUDIT; timeline follow back, TLFB), quality of life (EQ-5D-5L) and functionality (FAST). Several measure were taken at months 1, 3 and six: being active in the treatment at the assessment point (retention); adherence; alcohol and other substance use (TLFB) quality of life and functionality.
Results: The final sample consisted of 82 patients, with a mean age of 55.3 (SD = 11.4). 38.2 % were women, and 53% of the participants were allocated to the experimental group.

Image 1:

VARIABLE	Experimental group	Control group	Statistic (p-value)
Retention month 6 (Primary outcome)	76.7%	40%	Chi = 12.24 (0.002)*
Retention month 1	81.4%	69.4%	Chi = 2.1 (0.34)
Retention month 3	72.1%	41.7%	Chi = 8.24 (0.02)*
Median of attended visits (SD)	4.5 (2.2)	2.7 (2.46)	2.3 (0.002)*
Adherence (attended visits/scheduled visits)	74.4%	45.2%	

Image 2:

VARIABLE	Experimental group	Control group	Statistic (p-value)
Prevalence of alcohol use month 1	38.3%	44%	Chi = 1.17 (0.56)
Prevalence of alcohol use month 3	22.2%	54.2%	Chi = 5.55 (0.019)
Prevalence of alcohol use month 6	20%	48%	Chi = 5.6 (0.024)

Conclusions: MyWayUp has shown efficay in improving treatment retention and adherence as well as in improving abstinence rates.

Introduction: Alexithymia, the limited ability to recognize and describe emotions, reflects impairments in emotional awareness and is a prevalent dysfunctional trait in individuals with addiction. Pain is an interoceptive feeling processed through interoceptive pathways and serves as a homeostatic emotion that can motivate behavior. Pain sensitivity may play a role in the development and progression of alcohol use disorder (AUD). Interoceptive awareness (IA) refers to the ability to perceive the internal state of the body. Both interoceptive accuracy (IAc) and interoceptive sensibility (IS), the objective and subjective dimensions of IA, have been shown to be implicated in individuals with AUD.
Objectives: Our objective was to compare alexithymia, pain sensitivity, IAc, and IS levels between abstinent patients with AUD and healthy controls. Additionally, we aimed to investigate the potential associations between the dimensions of IA and both alexithymia and pain sensitivity.
Methods: The study comprised 52 abstinent patients with AUD and 52 healthy control subjects. 92.3% (n=48) of the participants in each group were male, and 7.7% (n=4) were female. Alexithymia was assessed using the 20-item Toronto Alexithymia Scale (TAS-20). Pain sensitivity was measured with the Pain Sensitivity Questionnaire (PSQ). IAc was assessed using the heart rate tracking task, which measured participants' awareness of their own heartbeat by comparing the number of heartbeats they perceived with an objective heart rate measurement. IS was evaluated using the Multidimensional Assessment of Interoceptive Awareness Version 2 (MAIA-2). The study included patients who had completed detoxification and been abstinent for at least three weeks while participating in or undergoing a 28-day abstinence-based inpatient treatment program.
Results: Individuals with AUD scored significantly higher on self-reported measures of alexithymia (AUD group: 53.35 ± 11.83; control group: 44.63 ± 6.43; $p < 0.001$, $F = 21.768$) and significantly lower on the heart rate tracking task (IAc) (AUD group: 0.65 ± 0.15; control group: 0.84 ± 0.13; $p < 0.001$, $F = 43.615$). No significant difference was found in self-reported IS scores (AUD group: 114.06 ± 21.38; control group: 113.37 ± 13.52; $p = 0.844$, $F = 0.039$) or pain sensitivity scores (AUD group: 5.22 ± 1.67; control group: 5.18 ± 1.06; $p = 0.892$, $F = 0.018$). Alexithymia scores showed significant negative correlations with IAc scores ($r = -0.256$, $p = 0.009$) and IS scores ($r = -0.361$, $p < 0.001$). However, pain sensitivity scores did not significantly correlate with alexithymia ($r = 0.083$, $p = 0.402$), IAc ($r = -0.103$, $p = 0.299$), or IS scores ($r = 0.136$, $p = 0.169$).
Conclusions: Our findings support the hypothesis that alexithymia, which is linked to the development and progression of AUD, is associated with the dimensions of IA.

doi: 10.1192/j.eurpsy.2025.434

Introduction: Treatment motivation is very important in the treatment of alcohol and substance use disorders. The evaluation of motivation, which is seen as the first step in addiction treatment, will also help understand the person's interest and compliance with treatment. The lack of motivation of the person during the treatment process causes treatment abandonment and relapses.
An important issue in the treatment of alcohol use disorder is the trust of the person in the treatment. It is also important for the addict to have someone around him who has benefited from treatment, which is very important in terms of treatment compliance. With the influence of a person who has benefited from addiction treatment, the likelihood of applying for treatment and benefiting from treatment increases in a "snowball" manner.
Objectives: The aim of this study was to evaluate whether people who are treated for alcohol use disorder have a treatment motivation for those around them. It was aimed to examine whether the people who have been treated are important in increasing the trust in treatment for other patients.
Methods: The study included cases who applied to the Seferihisar State Hospital Psychiatry Outpatient Clinic with complaints of alcohol use. The sociodemographic information form was filled out during the individuals' first applications. The participants were asked whether there were people around them who had received inpatient treatment for alcohol use disorder at the hospital where the study was conducted, and the individuals were then administered the Readiness for Change and Desire for Treatment Scale (SOCRATES), Treatment Motivation Questionnaire (TMQ), and Alcohol Use Disorders Identification Test (AUDIT). The individuals were given the standard treatment recommended in our country's treatment guidelines for the diagnosis of alcohol use disorder. The individuals participating in the study were interviewed at 1 month, 2 months and 3 months after starting treatment. The individuals' answers and the decrease in the frequency and amount of alcohol use were recorded.
Results: The rate of treatment attendance is 2.7 times higher for people who have received treatment for alcohol use disorder in their circle.
The rate of treatment confidence in treatment is 4.1 times higher for people who have received treatment for alcohol use disorder in their circle.
The frequency and amount of alcohol use has decreased more for people who have received treatment for alcohol use disorder in their circle.

Conclusions: It has been determined that those who are surrounded by people who have received treatment for alcohol use disorder have higher levels of treatment confidence and compliance. The assistance of these people to those around them can play an important role in increasing the success of addiction treatment.

doi: 10.1192/j.eurpsy.2025.435

Introduction: Treatment for bipolar disorder (BD) predominantly focuses on psychopharmacology, including lithium, antipsychotics, and anticonvulsants. Electroconvulsive therapy (ECT) is highly effective for managing manic or depressive episodes, yet studies on the effects of anticonvulsant therapy as a modifying factor of clinical outcome during ECT are scarce.
Objectives: To evaluate how concurrent anticonvulsant use affects seizure parameters and clinical outcomes of ECT in BD patients.
Methods: A comprehensive search of multiple databases (MEDLINE, Embase, Web of Science, PsycINFO, Cochrane Central Register of Controlled Trials, World Health Organization International Clinical Trials Registry Platform, ClinicalTrials.gov) was conducted on October 2, 2024, without language or publication date restrictions. Eligible studies included clinical trials and retrospective analyses comparing BD patients undergoing ECT with and without anticonvulsant use. Random-effects models were applied for a sufficient number of studies, while fixed-effects models were used for fewer studies. Subgroup and sensitivity analyses were conducted.
Results: Six studies met the criteria, involving 359 participants (mean age: 29.7 years; 31.2% female). Five studies focused on the effect of concomitant treatment with valproate during a manic episode, and only one study included subjects in treatment with other anticonvulsants during different mood episodes of BD. Anticonvulsant users required significantly higher minimal electrical dosages to achieve adequate seizures (SMD = 0.71, 95% CI [0.46 to 0.95], $p < 0.0001$), as indicated by higher seizure thresholds and stimulus doses. Additionally, anticonvulsant use was associated with a significantly shorter seizure duration (SMD = -0.75, 95% CI [-1.10 to -0.41], $p < 0.0001$). However, no significant differences in symptomatic improvement were found between those using and not using anticonvulsants (SMD = 0.03, 95% CI [-0.19 to 0.25], $p = 0.78$).
Conclusions: Concurrent anticonvulsant use in BD patients undergoing ECT is associated with higher seizure thresholds and shorter seizure durations, but this does not affect clinical outcomes regarding disease severity. Based on these findings, discontinuation of anticonvulsants during ECT may not be necessary. This review was limited by the small number of studies, small sample sizes, and considerable heterogeneity. Additionally, the majority of the studies analyzed only included patients in the manic state of the illness. Further research is needed to explore whether variations in seizure parameters are linked to individual clinical outcomes in BD patients, the impact of different anticonvulsants on these parameters and the outcome for depressive and mixed episodes of bipolar disorder.

Neurocognitive Profiles of Mood Phases in Bipolar Disorder: Is Agitated Depression Related to Mania or Depression?

F. Bardi[1]*, A. Restaino[1], E. De Chiara[1], C. Calderoni[1], F. Grisoni[1], G. Mandracchia[1], A. M. D'Onofrio[1], S. Margoni[1], G. Sani[1,2] and A. Simonetti[1]

[1]Fondazione Policlinico Universitario Agostino Gemelli IRCCS and [2]Università Cattolica del Sacro Cuore, Rome, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.436

Introduction: Agitated Depression (AgD) is a unique subtype of depression marked by impulsivity, higher suicide risk, treatment resistance, and worse clinical outcomes compared to Non-Agitated Depression (Non-AgD). Despite these clinical distinctions, the underlying neuropsychological mechanisms that differentiate AgD from Non-AgD remain poorly defined.
Objectives: This study aims to explore the neurocognitive correlates that differentiate AgD from Non-AgD.

Methods: The study cohort included 722 participants, divided into five groups: AgD, Non-AgD, subjects in a manic state (Mnc), euthymic subjects with bipolar disorder (Eu), and healthy controls (HC). All participants underwent a comprehensive neurocognitive assessment including the Wisconsin Card Sorting Test (WCST), the Interference Component of the Stroop Test (ST), the Semantic Fluency Test (SFT), the Trail-Making Test A and B (TMT-A, TMT-B), and Raven's Progressive Matrices (RPM). Data were analyzed using one-way ANOVAs and Tukey post-hoc tests to compare cognitive performance across groups.
Results: Non-AgD showed inferior performance compared to AgD on the WCST (non-perseverative errors: p=0.037; perseverative errors: p=0.010; categories identified: p=0.026), ST (p=0.000), TMT-A (p=0.046), and TMT-B (p=0.001). Non-AgD also underperformed Mnc at ST (p=0.002), SFT (p=0.025), TMT-A (p=0.007), TMT-B (p=0.005), and RPM (p=0.012). HC consistently outperformed AgD, Non-AgD, Mnc, and Eu individuals on all neurocognitive tests except for the WCST, where no significant differences were observed between HC, Eu, and AgD. Eu demonstrated superior performance on the WCST (p≤0.001), ST (p=0.000), and TMT (p=0.000) compared to Non-AgD, with no significant differences compared to AgD.
Conclusions: The findings reveal distinct neurocognitive profiles for AgD and Non-AgD. The excitatory mechanisms associated with AgD may contribute to enhance attentional resources and cognitive flexibility but also greater impulse control difficulties. The neuropsychological profile of Eu patients resembles that of AgD, suggesting residual cognitive differences compared to HC. This study enhances our understanding of AgD by highlighting the differences in cognitive profiles of AgD, Non-AgD, Mnc, and Eu, and emphasizing the need of considering neurocognitive factors in the characterization and treatment of AgD.

Introduction: Lumateperone, an atypical antipsychotic drug, has a dual mechanism of action by combination of activity at central serotonin (5-HT2A) and dopamine (D2) receptors.
Objectives: This subgroup analysis of an Indian Phase 3 study was conducted to evaluate the efficacy and safety of Lumateperone 42mg compared to Quetiapine 300mg in treatment of Bipolar II depression when stratified based on baseline body mass index (BMI).
Methods: The phase-III, randomized, multi-centric, assessor-blind, parallel-group, active-controlled, comparative, non-inferiority study included patients with Bipolar II depression with moderate severity having a Montgomery-Asberg depression rating scale (MADRS) score ≥20 and Clinical global impression–bipolar version–severity (CGI-BP-S) score ≥4. The study was conducted after receiving regulatory and ethics committee approvals. The patients were randomized (1:1) to either receive Lumateperone 42mg [Test] or Quetiapine 300mg [Comparator] for 6 weeks. The patients were stratified based on baseline BMI: Subgroup 1 [S1]: <25Kg/m^2 and Subgroup 2 [S2]: ≥25Kg/m^2. For efficacy outcomes MADRS score, CGI-BP-S (total score, depression subscore and overall bipolar illness subscore), and Quality of life enjoyment and satisfaction-short form questionnaire (Q-LES-Q-SF) score were evaluated and for safety outcomes treatment emergent adverse events (TEAEs) were assessed. [Clinical trial registration: CTRI/2023/10/058583]
Results: This subgroup analysis included 462 patients, out of which 276 in S1[Test=139; Comparator=137] and 186 in S2[Test=92; Comparator=94]. The baseline demographic characteristics were comparable in between treatment arms across subgroups. The primary endpoint of reduction in MADRS score from baseline to Day 42 in Test arm was non-inferior to Comparator arm in both subgroups [Figure 1] as the upper 95% CI was below the pre-defined margin of 3.0. The reduction of CGI-BP-S (total score, depression subscore and overall bipolar illness subscore) from Day 14 to Day 42 were comparable in both Test and Comparator arms in both subgroups. The improvement in Q-LES-Q-SF score from baseline to Day 42 were comparable in both Test and Comparator arms in both subgroups. The incidence of TEAEs were similar in both treatment arms [S1: Test=38.1% and Comparator=36.5%; S2: Test=29.3% and Comparator=34.0%] and no serious adverse events were reported.

Image 1:

Conclusions: This subgroup analysis demonstrated that Lumateperone 42mg is non-inferior to Quetiapine 300mg in treatment of Bipolar II depression as assessed via MADRS score from baseline to Day 42, irrespective of baseline BMI and both treatments were found to be well tolerated. Hence, Lumateperone can be considered as valuable treatment option in management of Bipolar II depression.

Insulin Resistance and Suicidal Behaviors: Insights into Mood Disorders

L. Raffaelli[1]*, E. Mazza[1], C. Gaggi[1], C. Lorenzi[1] and F. Benedetti[1]

[1]IRCCS Ospedale San Raffaele, Milan, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.439

Introduction: Compared to the general population, mood disorders (MD) patients show an increased risk of developing type II diabetes and obesity, which are associated with changes in brain correlates and a worse clinical outcome[1]. According to the literature, MD patients with a dysregulated metabolic system are characterized by a reduction in white matter (WM) integrity, lower global functioning, and suicidal behaviors (SB) [2],[3],[4]. However, little is known about the impact of early stages of metabolic dysregulation, namely insulin resistance (IR), in relation to the clinical course of MD[1].
Objectives: Therefore, the present study aims to investigate the effect of IR on WM integrity in MD patients with suicidal behaviors (s-BP, s-UP) compared to those without suicidal behaviors (ns-BP, ns-UP). Finally, we have hypothesized that obesity may be linked to SB through a biological pathway involving inflammatory and IR markers.
Methods: Our sample was composed of 184 depressed patients (92 BP, 92 UP) who were assessed for SB via the Beck Suicidal Scale (BSS). Patients underwent 3T Magnetic Resonance imaging, and blood samples were collected to determine levels of insulin and glucose and blood cell counts. The Homeostatic Model Assessment for Insulin Resistance (HOMA) and systemic-immune-inflammation index (SII) were then computed. To investigate the effect of HOMA and SII on WM microstructure, we performed voxelwise DTI analyses: first, we tested whether the relation between HOMA, SII, and DTI measures differed between s-BP and ns-BP patients; then, post-hoc analyses were performed for analyzing the effect of HOMA, and SII separately in 40 s-BP and 52 ns-BP. The same analyses were replicated on 43 s-UP and 49 ns-UP. Moderated mediation analyses were performed with the macro PROCESS for SPSS.
Results: The relationship between BMI and suicidal behaviors was fully serial mediated by SII and HOMA only in BP (b=0,031, 95% BCa CI [0.003, 0.088]). Specifically, we found that higher BMI was sequentially associated with increased SII and HOMA levels, ultimately leading to higher BSS scores. A significant interaction between s-BP and ns-BP was identified for the effect of (1) HOMA on mean diffusivity (MD), axial (AD), and radial diffusivity (RD). However, no significant interaction was found for the effect of IR and SII markers in UP. Performing the analyses separately in the two groups, s-BP showed (1) a negative widespread association between HOMA and FA, and a positive effect between HOMA and RD, AD, and MD. In ns-BP, no significant results were found.
Conclusions: These findings may suggest that IR may play a key role in the biological pathway underlying suicidal behaviors in BP but not in UP. Therefore, metabolic system dysregulation should be taken into consideration during the treatment.

doi: 10.1192/j.eurpsy.2025.440

Introduction: Lumateperone, an atypical antipsychotic drug, has a dual mechanism of action by combination of activity at central serotonin (5-HT2A) and dopamine (D2) receptors.
Objectives: This subgroup analysis of an Indian Phase 3 study was conducted to evaluate the efficacy and safety of Lumateperone 42mg compared to Quetiapine 300mg in treatment of Bipolar II depression when stratified based on prior hypomanic episodes.
Methods: The phase-III, randomized, multi-centric, assessor-blind, parallel-group, active-controlled, comparative, non-inferiority study included Indian patients with Bipolar II depression with moderate severity having a Montgomery-Asberg depression rating scale (MADRS) score ≥20 and Clinical global impression–bipolar version–severity (CGI-BP-S) score ≥4. The study was conducted after receiving regulatory and ethics committee approvals. The patients were randomized (1:1) to either receive Lumateperone 42mg [Test] or Quetiapine 300mg [Comparator] for 6 weeks. The patients were stratified based on number of prior hypomanic episodes in lifetime: Subgroup 1 [S1]: 1 episode and Subgroup 2 [S2]: >1 episode. For efficacy outcomes MADRS score, CGI-BP-S (total score, depression subscore and overall bipolar illness subscore), and Quality of life enjoyment and satisfaction-short form questionnaire (Q-LES-Q-SF) score were evaluated and for safety outcomes treatment emergent adverse events (TEAEs) were assessed. [Clinical trial registration: CTRI/2023/10/058583]
Results: This subgroup analysis included 462 patients, out of which 251 in S1[Test=129; Comparator=122] and 211 in S2[Test=102; Comparator=109]. The baseline demographic characteristics were comparable in between treatment arms across subgroups. The primary endpoint of reduction in MADRS score from baseline to Day 42 in Test arm was non-inferior to Comparator arm in both subgroups [Figure 1] as the upper 95% CI was below the predefined margin of 3.0. The reduction of CGI-BP-S (total score, depression subscore and overall bipolar illness subscore) from Day 14 to Day 42 were comparable in both Test and Comparator arms in both subgroups. The improvement in Q-LES-Q-SF score from baseline to Day 42 were comparable in both Test and Comparator arms in both subgroups. The incidence of TEAEs were similar in both treatment arms [S1: Test=37.2% and Comparator=35.2%; S2: Test=31.4% and Comparator=35.8%] and no serious adverse events were reported.

Image 1:

Conclusions: This subgroup analysis demonstrated that Lumateperone 42mg is non-inferior to Quetiapine 300mg in treatment of Bipolar II depression as assessed via MADRS score from baseline to Day 42, irrespective of number of previous hypomanic episodes and both treatments were found to be well tolerated.

Differences in Electrodermal Activity in Depressed Bipolar Patients with High and Low Anxiety Levels

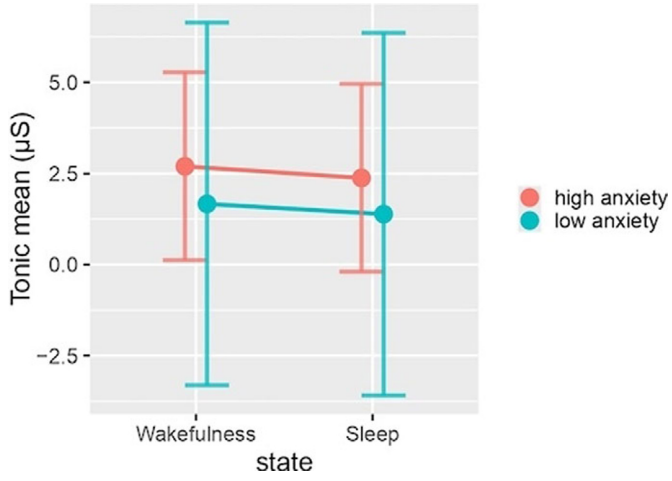
C. Valenzuela-Pascual[1,2,3]*, D. Hidalgo-Mazzei[1,2,3], A. Mas[1,2,3], G. Anmella[1,2,3], F. Corponi[4] and E. Vieta[1,2,3]

[1]Department of Psychiatry and Psychology, Hospital Clínic de Barcelona; [2]Bipolar and Depressive Disorders Unit, Institut d'Investigacions Biomèdiques August Pi I Sunyer (IDIBAPS); [3]Department of Medicine, School of Medicine and Health Sciences, Institute of Neurosciences (UBNeuro), University of Barcelona (UB), Barcelona, Spain and [4]School of Informatics, University of Edinburgh, Edinburgh, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.441

Introduction: Electrodermal activity (EDA) measures the skin's electrical properties. It varies according to the sweat gland's activity which responds to the sympathetic nervous system (Boucsein W. Electrodermal Activity. Berlin: Plenum Press; 2012). Previous literature has reported lower EDA during bipolar and unipolar depressive episodes (Sarchiapone M, et al. BMC Psychiatry 2018; 18: 22 & Valenzuela-Pascual C, et al. Acta Psychiatr Scand 2024). Historically, heightened anxiety has been correlated with increased EDA, although findings in this area have been inconsistent (Naveteur J, et al. Int J Psychophysiol 2005; 56(3): 261–269).
Objectives: This study aimed to determine whether significant differences in EDA exist among depressed patients based on their levels of anxiety.
Methods: We analysed EDA recordings from an E4 wearable device utilised by 29 depressed patients with bipolar disorder. They wore the device for a period of 48 hours without altering their daily routines. The tonic mean and phasic peaks parameters of EDA were extracted and analysed via a mixed-effects model for repeated measures, incorporating sleep state and anxiety level as variables. Anxiety levels were assessed based on the scores from item 10 on the Hamilton Rating Scale for depression, which reflects psychic anxiety.

Results: The results indicated that anxiety levels did not significantly influence any of the models examined. However, in the phasic peaks model, there is a noteworthy interaction between anxiety level and sleep status ($p < 0.01$). Both models demonstrated a tendency towards increased EDA values in the high anxiety group although these findings did not reach statistical significance. This trend was consistent across both sleep states for the tonic mean model (Image 1). In contrast, the high anxiety group exhibited higher phasic peaks values (M [SD] = 2.33 [0.80-3.86]) compared to the low anxiety group (M [SD] = 2.33 [0.80-3.86]) only during wakefulness, although this difference was not statistically significant ($p > 0.05$) (Image 2).

Image 1:



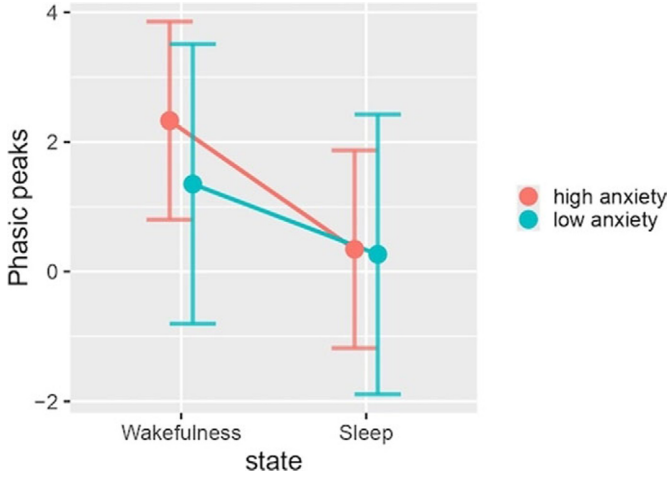


Image 2:

Conclusions: These findings should be interpreted with caution due to the small sample size and the imbalance in the distribution of low (17%) versus high anxiety (83%) participants. Furthermore, anxiety is a multifaceted symptom that should be evaluated using a more comprehensive assessment tool. To validate these preliminary observations, it is essential to increase the sample size and use a more precise measure of anxiety.

Do Second-Generation Antipsychotics Protect Against the Emergence of (Hypo)mania in Depressed Patients with Mixed Features?

M. Zimmerman

Brown University, ProvidencePPPPro, United States
doi: 10.1192/j.eurpsy.2025.442

Introduction: Five medications have been approved for the treatment of bipolar depression, though no medication has been approved for the treatment of depression with mixed features. Post-hoc analyses of the bipolar depression trials examined efficacy in depressed patients with and without mixed features. Each study also examined the emergence of manic symptoms as a possible negative outcome, and each found that the frequency of emergent manic symptoms was more frequent in the patients treated with placebo than with medication though in no study was the difference statistically significant. However, the studies were not powered to detect a significant difference in treatment emergent (hypo)manic episodes thereby prompting the current pooled analysis.

Objectives: The goal of the present pooled analysis was to examine whether second-generation antipsychotics that have been found effective in treating depression with mixed features protect against the emergence of (hypo)manic episodes in depressed patients with concurrent manic symptoms.

Methods: Five placebo-controlled studies of the effectiveness of second-generation antipsychotics in the treatment of depressed patients with mixed features reported information on the emergence of manic symptoms.

Results: The 5 studies included 1,829 depressed patients with mixed features—1,620 with bipolar disorder and 209 with major depressive disorder. In each study, the frequency of treatment-emergent manic episodes was higher in the group treated with placebo, though in no study was this difference significant. Summed across studies, the frequency of treatment emergent (hypo)manic episodes was higher in the patients receiving placebo (4.0% vs. 2.4%, X^2=3.66, p=.056). Excluding the patients treated with olanzapine, which has not been found to be effective in treating bipolar depression, the frequency of emergent (hypo)manic episodes was significantly higher in the patients receiving placebo, (4.0% vs. 1.8%, X^2=7.31, p=.007).

Conclusions: The results of the present analysis suggest that the second-generation antipsychotics that are effective in treating bipolar depression also protect against a (hypo)manic switch in depressed patients with mixed features.

Cyberbullying Among Middle School Students in Sousse, Tunisia: Prevalence and associated factors

R. Ayoub[1]*, N. E. Ayadi[1], H. Ben Abid[1], A. Riahi[1], K. Faidi[1] and A. Guedria[1]

[1]Child and Adolescent Psychiatry Department, Fattouma Bourguiba university Hospital- University of Monastir, Monastir, Tunisia

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.443

Introduction: With the increased exposure to social media and the widespread use of technological tools, adolescents are at higher risk of engaging in cyberbullying. Cyberbullying is a specific form of bullying, characterized by persistent aggressive behavior, an imbalance of power, and an intent to cause harm. It occurs through electronic communication, including social media platforms, messaging apps, and other online spaces. In Tunisia, limited data exists on the extent and characteristics of cyberbullying, particularly in the of Sousse.
Objectives: Our study aims to assess the prevalence of cyberbullying among middle school students in the Sousse region and identify the factors associated with this phenomenon.
Methods: This is a cross-sectional, descriptive, and analytical study based on a survey conducted among adolescents attending two middle schools in the governorate of Sousse during the 2020/2021 school year. The participants completed a demographic information sheet, the "Cyberbullying Screening Test," and the "Resilience Factors Inventory (IFR-40) "
Results: Our population consisted of 238 adolescents, with 63.6% girls and 36.4% boys, giving a sex ratio of 0.57. The average age of participants was between 13 and 15 years old. Our results showed that 38.2% of adolescents used their phones or computers for more than three hours per day, and 32.4% used social media for over three hours daily. The prevalence of cyber victimization was 51.3% within our population. Familial protective factors were present in 80.6% of the sample, individual protective factors in 76.5%, and social protective factors in 68.7%. Our analysis revealed that repeating a grade was statistically associated with cyberbullying (p-value = 0.002). Furthermore, familial protective factors and individual protective factors were significantly correlated with cyberbullying, with p-values of 0.007 and 0.019, respectively. However, no significant association was found with social protective factors (p-value = 0.3).
Conclusions: Our study confirms the concerning extent of cyberbullying among Tunisian adolescents and highlights the need to develop appropriate prevention and intervention strategies to improve youth well-being. Enhancing family and individual resilience appears to be a promising approach for preventing cyberbullying and supporting affected adolescents.

doi: 10.1192/j.eurpsy.2025.444

Introduction: Bullying is a persistent aggressive behavior characterized by a power imbalance and driven by the intent to cause harm. Examining the connection between past experiences of victimization and current bullying behaviors is essential for a comprehensive understanding of this phenomenon..
Objectives: This study aims to assess the prevalence of bullying and cyberbullying among Tunisian adolescents and to explore the relationship between current bullying behaviors and a history of childhood victimization.
Methods: This cross-sectional study was conducted via a survey among adolescents attending middle and high schools during the 2023-2024 school year. Participants provided written consent and completed a demographic information sheet, the Adolescents and Peer Relations Instrument (APRI), and the Adverse Childhood Experience-International Questionnaire (ACE-IQ).
Results: The study population consisted of 1,005 adolescents, with a sex ratio of 0.73 and a mean age of 14.62 years. We find that 92.1% of adolescents experienced traditional bullying within the year, with 54.9% exposed to school bullying more than once a month. The most prevalent form was verbal bullying (88%), followed by relational bullying (77.3%) and physical bullying (73.9%). Among the participants, 38.5% had no history of past bullying but were currently victimized, 53.7% had experienced bullying in the past and continued to be victimized, 1.3% had been victimized in the past but no longer experienced bullying, and 6.5% had never been bullied, either in the past or present.
We identified a significant association between peer violence and bullying victimization, with a p-value <0.001 and an odds ratio (OR) of 4.11 (95% CI: 2.5-6.66). There was also a significant correlation between peer violence and the APRI scale ($p < 0.001$). Further analysis showed a strong correlation between peer violence and verbal bullying victimization ($p < 0.001$, OR = 3.75 [2.53-5.56]), relational bullying victimization ($p < 0.001$, OR = 2.8 [2.1-3.8]), and physical bullying victimization ($p < 0.001$, OR = 2.64 [1.97-3.53]). The risk of being victimized by all three forms of bullying was tripled ($p < 0.001$, OR = 2.75 [2.1-3.6]).
Conclusions: This study highlights the alarmingly high prevalence of bullying among Tunisian adolescents and emphasizes the significant link between past victimization and current bullying experiences. These findings underscore the need for targeted interventions that address the underlying trauma from past experiences to promote positive youth development.

Psychopathological Profiles of Adolescent Suicide Attempters: A Comprehensive Analysis

A. Garcia Fernandez[1], C. Martínez-Cao[1], I. Pérez-Díez[2], J. Andreo-Jover[3], W. Ayad-Ahmed[4], A. I. Cebriá[5], A. González-Pinto[6], I. Grande[7], M. Ruiz Veguilla[8] and P. A. Sáiz[1]*

[1]Universidad de Oviedo, Oviedo; [2]Universidad Autónoma; [3]Hospital Universitario La Paz; [4]Universidad Complutense, Madrid; [5]Hospital Parc Taulí, Sabadell; [6]Hospital Universitario Araba, Vitoria; [7]Hospital Clinic, Barcelona and [8]Hospital Virgen del Rocio, Sevilla, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.446

Introduction: Despite the identification of several risk factors, an understanding of the role of specific psychopathological profiles in predicting adolescent suicidal behaviours remains a key challenge in public health research.
Objectives: The current study aimed to identify psychopathological profiles in suicidal adolescents and to analyse their association with suicide-related outcomes.
Methods: A total of 285 adolescents aged 12 to 17 years [mean age (SD)=14.98 (1.51); females: 249 (87.40%)] were recruited from different hospitals in Spain. Latent profile analysis was performed to classify subgroups with similar patterns based on self-report Strengths and Difficulties Questionnaire. Logistic regression and generalised linear modelling were applied to examine the relationship between profile membership and suicidal behaviours.
Results: Three psychopathological profiles were identified: internalizing symptom profile (52.63%), externalizing symptom profile (24.21%), and low symptom profile (25.58%). The predominantly female internalizing symptom profile members were more likely to report higher levels of psychopathological symptoms, including number of psychiatric diagnoses, depressive symptoms, and trauma (except sexual abuse). Additionally, they had more non-suicidal self-injury (NSSI) and suicidal thoughts and behaviours. Likewise, greater ideation intensity was associated with the internalizing symptom profile compared to other groups, while greater number of previous suicide attempts correlated with an increase in suicidal behaviours. Finally, higher levels of motor impulsivity were associated with a lower probability of suicidal behaviours.
Conclusions: Identifying symptom profiles among adolescents who have attempted suicide allows us to establish reliable predictors for suicide prevention as well as personalised interventions, indicating the domains where these interventions are needed.

The moderating role of hippocampus-dorsolateral prefrontal cortex resting-state functional connectivity in the relationship between emotional abuse and depression in adolescents

K. H. Lee[1]*, J. Shin[2], J. Lee[3], J. H. Yoo[4] and J.-W. Kim[1]

[1]Psychiatry, Seoul National University Hospital, Seoul; [2]Psychiatry, Eulji University School of Medicine, Uijeongbu; [3]Integrative Care Hub, Seoul National University Children's Hospital and [4]Psychiatry, The Catholic University of Korea, Seoul ST. Mary's Hospital, Seoul, Korea, Republic Of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.447

Introduction: Early life adversity (ELA) such as physical and emotional abuse has been recognized as an important risk factor for depression in adults. Past research has shown that ELA was associated with alteration in the hippocampus, a key region involved in stress sensitivity, emotional learning and memory. However, relatively little is known about the role of the hippocampus in the relationship between ELA and depression in adolescents.
Objectives: This study aimed to investigate whether the hippocampal volume and hippocampus resting-state functional connectivity (RSFC) moderated the relationship between ELA and depressive symptom severity in adolescents with major depressive disorder (MDD).
Methods: This study included 73 adolescents with MDD (age M (SD) = 15.0 (1.5) years, 51 girls). The participants completed the Early Trauma Inventory and Children's Depression Rating Scale to assess ELA and depressive symptom severity, respectively. Resting–state functional and structural T1 images were collected using a Siemens 3T MR scanner and preprocessed using AFNI and FreeSurfer routines. The average BOLD time-series was extracted from our regions-of-interest (ROIs), the bilateral hippocampus and dorsolateral prefrontal cortex (DLPFC). An ROI-to-ROI RSFC analysis was conducted to calculate Pearson correlation coefficients between the hippocampus and DLPFC ROIs. The correlation coefficients were transformed to Fisher's z. We performed correlation and moderation analyses to test our moderation model (Figure 1) after controlling for age and sex.
Results: Emotional abuse, one form of ELA, was significantly correlated with depressive symptoms in adolescents with MDD (r = 0.25, p < .05). Bilateral hippocampus – left DLPFC RSFCs moderated the association between emotional abuse and depressive symptoms in adolescents with MDD (ps < .01). The association between emotional abuse and depressive symptoms was stronger when bilateral hippocampus – left DLPFC RSFCs were lower (left hippocampus – left DLPFC RSFC, -1D: b = 3.72, SE = 1.06, p < .001; right hippocampus – left DLPFC RSFC, -1D: b = 4.15, SE = 1.04, p < .001) than when they were greater (left hippocampus – left DLPFC RSFC, +1D: b = -0.09, SE = 1.05, p = .93; right hippocampus – left DLPFC RSFC, +1D: b = -0.10, SE = 0.98, p = .69) (Figure 2). Hippocampal volumes also moderated the relationship between emotional abuse and depressive symptoms, but the results did not remain significant after correcting for multiple comparisons.

Image 1:

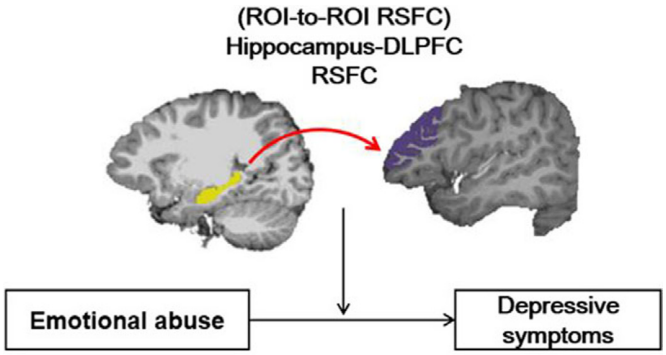

Figure 1. A proposed moderation model, ROI, region of interest; DLPFC, dorsolateral prefrontal cortex; RSFC, resting-state functional connectivity

Image 2:

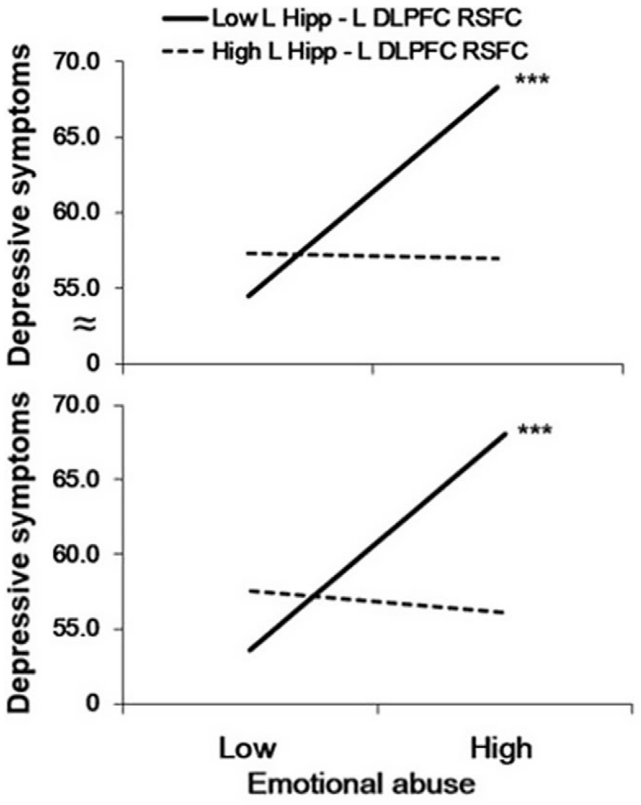

Figure 2. Emotional abuse x bilateral hippocampus – left DLPFC RSFCs predicting depressive symptoms (*** $p < .001$). RSFC, resting-state functional connectivity; R Hipp, right hippocampus; L Hipp, left hippocampus; L DLPFC, left dorsolateral prefrontal cortex

Conclusions: Our findings suggest the important role of hippocampus RSFC with the DLPFC in the relationship between emotional abuse and depressive symptoms in adolescents with MDD.

Impact of ADHD Subtypes, Cognitive Disengagement Syndrome and Anxiety on Memory Functions and Visuospatial Skills in Children with ADHD

I. Adak[1], E. Özdeniz Varan[2], Ö. Ekinci[1], Z. Durmuş[1], N. Kılıç[1], A. Alpman[1]*, O. B. Karakuş[3] and I. Süzer Gamlı[1]

[1]Child and Adolescent Psychiatry, Erenköy Mental and Nervous Diseases Training and Research Hospital; [2]Clinical Psychology, University of Health Sciences and [3]Child and Adolescent Psychiatry, Trabzon Provincial Health Directorate Kanuni Training and Research Hospital, İstanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.448

Introduction: Children with Attention Deficit Hyperactivity Disorder (ADHD) may experience impairments in memory functions and visuospatial skills. Despite this, research exploring the relationship between ADHD subtypes, psychiatric comorbidities, and these neurocognitive functions is limited. This study focused on cognitive disengagement syndrome (CDS) and anxiety as comorbid conditions, both of which independently impact neurocognitive functions. However, the combined effects of these conditions with ADHD remain poorly understood. Moreover, investigating how CDS influences neurocognitive domains is essential for a comprehensive understanding of the syndrome's cognitive aspects. Therefore, identifying the factors that impact memory functions and visuospatial skills in children with ADHD is expected to facilitate the recognition of cases at risk.
Objectives: This study aimed to investigate the relationship between ADHD subtypes, psychiatric comorbidities, and memory functions and visual spatial skills in children with ADHD.
Methods: The study recruited 120 children with ADHD aged 6-12 years. ADHD subtypes, anxiety, and CDS symptoms were assessed using standardized scales and DSM-5-based psychiatric evaluations. The participants were then administered the Visual Reproduction Subtest of the Wechsler Memory Scale, Oktem Verbal Memory Processes Test , Block Design Subtest of the WISC-IV, Judgment of Line Orientation Test and Benton Visual Recognition Test to measure visuospatial skills and working memory functions.
Results: The results showed that 28% of the sample group was diagnosed with inattentive type ADHD (ADHD-IN), while 72% were diagnosed with combined type ADHD. Additionally, 33.33% of participants had CDS+ADHD. When comparing children with CDS + ADHD to those with ADHD alone in terms of visual-spatial and organizational processing abilities, it was found that those with CDS + ADHD were impaired. Children with ADHD-IN also scored lower on a verbal memory test compared to those with combined-type ADHD. On the other hand, anxiety scores were found to be positively correlated with memory functions.
Conclusions: The study found that ADHD subtypes, the presence of CDS symptoms, and anxiety impact the neurocognitive profile of children with ADHD. Further research is needed to understand the various areas of cognitive function that may be affected. The authors declare that they have no conflicts of interest.

Can the Stroop Test Be Useful in Differentiating Specific Learning Disorder from Attention Deficit Hyperactivity Disorder?

H. A. Güler[1]*, F. U. Dündar[1], M. Kuz[2] and M. E. Tezcan[1]

[1]Department of Child and Adolescent Psychiatry, Selçuk University and [2]Special Clinic, Konya, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.449

Introduction: Specific Learning Disorder (SLD) is a significant comorbidity in children with Attention Deficit Hyperactivity Disorder (ADHD). Both ADHD and SLD are neurodevelopmental conditions that share common characteristics, such as deficits in executive functions. Identifying SLD in patients with ADHD is crucial because targeted educational interventions are the primary treatment for SLD.
Objectives: This study aimed to evaluate the utility of the Stroop Test (ST) in differentiating SLD from ADHD.
Methods: 79 patients (42 with ADHD and 37 with both ADHD and SLD) participated in the study. Sociodemographic information and ST performance metrics (completion time, omission errors, and commission errors) were collected by a child and adolescent psychiatrist. Additionally, parents completed the Turgay DSM-IV ADHD Rating Scale to assess the severity of ADHD symptoms.
Results: There were no significant differences between the ADHD and ADHD+SLD groups regarding age, gender, or ADHD symptom severity. The ADHD+SLD group exhibited longer completion times across all sections of the ST. Omission errors in the fourth and fifth sections were significantly higher in the ADHD+SLD group. After adjusting for age, gender, and ADHD symptom severity, the completion time in the fifth section and omission errors in the fourth and fifth sections remained significant. Receiver Operating Characteristic (ROC) analysis identified cut-off scores for the fifth section's completion time (42 seconds; Sensitivity: 0.62, Specificity: 0.66) and omission errors (1 error; Sensitivity: 0.64, Specificity: 0.61). Moreover, omission errors in the fifth section predicted being in the ADHD+SLD group (p= .006, Odds Ratio [OR]= 1.527, 95% CI= 1.127–2.068).
Conclusions: The findings suggest that the ST may be a valuable tool for diagnosing SLD in patients with ADHD. In particular, the completion time and omission errors in the fifth section of the ST may serve as practical diagnostic indicators. Further research with larger sample sizes is necessary to confirm these results.

Challenges and Parental Perspectives on Sexual Education for Children and Adolescents in Tunisia: A Cultural Insight

A. Hadj Salah[1]*, S. Iben Khedher[1], A. Haouala[1], I. Batbout[1], M. Ben Mbarek[1], F. Zaafrane[1], A. Mhalla[1] and B. Amamou[1]

[1]Psychiatry, Fattouma Bourguiba Hospital, Monastir, Tunisia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.451

Introduction: School-based sexual education aims to provide children and adolescents with the knowledge and values necessary for a positive view of their sexuality within their emotional and social development. However, sexual health education in Tunisian schools remains controversial, particularly among parents.
Objectives: To assess parents' perceptions of school-based sexual education and identify challenges related to sexual health education in Tunisia.
Methods: This descriptive study, conducted from September to October 2021, involved 154 parents from various Tunisian governorates. Participants completed a self-administered questionnaire in classical Arabic distributed via online groups. The survey explored perceptions of sexual education and identified key challenges.
Results: Of the participants, 55.8% (n=86) were aware of the national sexual education program, but only 13.6% (n=21) knew its content. A majority (81.8%; n=126) supported school-based sexual education. Key topics for discussion included the human body and its development (77.3%), moral values, rights, and culture (68.8%), and violence and safety (68.2%). Most parents preferred discussions to start in middle school (46.1%; n=71) or primary school (30.5%; n=47), with only 6.5% (n=10) advocating for earlier education.
Parents, healthcare professionals, and teachers were seen as primary educators (68.2%; n=105; 64.3%; n=99; 63%; n=97). While 55.8% recognized sexual rights as part of human rights, only 39.53% (n=34) were knowledgeable about these rights. Only 29.1% of parents (n=46) regularly discussed sexuality with their children. Despite the general value placed on sexual education and minimized concerns about negative consequences, some parents worried about risks such as early sexual activity. On a scale of 1 to 10, half of the participants (50%; n=77) rated the importance of sexual education at 8/10 or higher.
Conclusions: The study highlights the need for sexual education programs tailored to Tunisia's cultural context. Despite strong parental support (81.8%) and acknowledgment of essential topics like human development and moral values, only 13.6% are familiar with the program content. Challenges include concerns about cultural fit and potential negative impacts. Engaging parents, educators, and health professionals is crucial for overcoming these challenges. Further research should explore these cultural dynamics and assess.

The Impact of Parental Screen Time on Children's Mental Health. Systematic review and meta-analysis

A. Leonova[1]*, K. Markin[2], K. Vasilchenko[3] and E. Nemtseva[4]

[1]Pain Treatment Clinic, Tyumen; [2]S. M. Kirov Military Medical Academy, Saint Petersburg, Russian Federation; [3]The Human Artificial Control Keren (HacK) lab, Azrieli Faculty of Medicine, Bar-Ilan University, Safed, Israel and [4]Orenburg State Medical University, Orenburg, Russian Federation
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.452

Introduction: In the past decade, techno-referentiality has increasingly influenced daily life, illustrating how technology can disrupt human relationships. A notable example of this phenomenon is "phubbing"—a combination of "phone" and "snubbing"—which refers to the act of ignoring someone in favor of engaging with a mobile phone, leading to diminished eye contact and interest during face-to-face interactions. Recent research has highlighted

"parental phubbing," suggesting it may adversely affect parent-child relationships and contribute to developmental and mental health issues in children and adolescents.
Objectives: This study seeks to investigate the potential effects of parental phubbing on the mental health and development of children.
Methods: We conducted a systematic review and meta-analysis using Nested Knowledge software, adhering to PRISMA guidelines. Our search encompassed five databases: PubMed, Scopus, PsycINFO, Web of Science, and EBSCO. The inclusion criteria for studies were:• Cross-sectional or longitudinal design.

- Quantitative data on parental phubbing and its potential impact on children's mental health symptoms and developmental disorders.
- Studies involving children aged 0 to 18-21 years.
- Publications in peer-reviewed English-language journals.

The methodological quality and risk of bias in the included studies were assessed using the JBI Critical Appraisal Checklist. Publication bias was evaluated through funnel plot analysis and Egger's regression intercept. Meta-analyses were performed using Jamovi with the MAJOR module, applying the Fisher r-to-z transformation for correlation coefficients. A random-effects model was used, and heterogeneity was estimated with the restricted maximum-likelihood estimator. Sensitivity analyses were conducted to ensure the robustness of the findings.
Results: Our search identified 26 studies involving 22833 children and 2125 parents. We developed a unified theoretical model of the direct and mediating effects of parental phubbing on child mental health. The meta-analysis revealed that parental phubbing was significantly associated with:

- Increased affective symptoms in children (k=10; r=0.319; 95% CI [0.269, 0.370]).
- Higher levels of aggression or deviant behavior (k=3; r=0.260; 95% CI [0.134, 0.386]).
- Greater internalizing problems (k=4; r=0.242; 95% CI [0.166, 0.319]).
- More externalizing problems (k=4; r=0.158; 95% CI [0.081, 0.234]).

Additionally, parental phubbing was negatively correlated with children's self-esteem (r=-0.233; 95% CI [-0.315, -0.150]).
Conclusions: This meta-analysis underscores the significant harm that parental phubbing can inflict on children's emotional and social well-being. To safeguard and enhance children's development, it is crucial to implement strategies that promote more mindful technology use and foster stronger, more engaged parent-child relationships.

Between Sensitivity and Specificity – an analysis of the relationship between the clinical picture, diagnostic delays and co-morbidity among adolescents with autism spectrum disorders

K. M. Wilczyński[1]*, A. Stasik[2], L. Cichon[1], I. Jelonek[1] and M. Janas-Kozik[1]

[1]Department of Psychiatry and Psychotherapy of Developmental Age, Medical University of Silesia, Katowice and [2]Department of Psychiatry and Psychotherapy of Developmental Age, John Paul 2nd Child and Family Health Center , Sosnowiec, Poland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.453

Introduction: Early diagnosis of ASD a very important factor in improving the quality of life of people on the spectrum. Isolated reports that analyse the effect of age of diagnosis on the comorbidity indicate a statistically significant relationship between these parameters. However, the literature on this subject is very poor and does not take into account the risk of self-aggression and suicide in this context.
Objectives: In this two-stage study we have aimed to analyse the risk of comorbidity, specific diagnoses, and the risk of autoagression and suicidality depending on the age of diagnosis of ASD as well as we have tried to answer the question of what factors affect the age of diagnosis in Poland.
Methods: First stage of the study was carried out in the form of a retrospective analysis of the documentation and, in total, included the documentation of 328 people who comprised all patients with ASD diagnosis hospitalised in inpatient and diagnosed in outpatient clinic of our Department in 2021 and 2022. Subsequently in the second stage 77 children were randomly recruited among the patients with the diagnosis of ASD who came to local mental health clinic at the Child and Family Health Center in Sosnowiec for the more detailed analysis.
Results: In the first stage the mean age of diagnosis of ASD in the overall group was 11.28 years. The late diagnosis of ASD was also statistically significantly associated with the risk of psychiatric comorbidity. Furthermore in the logistic regression analysis, each subsequent year of diagnosis delay was statistically significantly associated with the risk of suicidal ideation with OR=1.29 (95%CI: 1.17-1.42; p<0.000001). Statistically significant parameters shaping the time of ASD diagnosis were: mutual communication, the ability to establish peer relationships and the appearance of atypical social behaviours. In the second stage of the study the mean age of the first enrollment in the mental health clinic was 9.09 years for girls and 6.42 for the boys. The age of the first visit to mental health clinic was correlated only with the total score of the ADOS-2 study (rho = -0.32; p = 0.0092) and the ADOS-2 social affect subscale (rho = -0.29; p = 0.012). Meanwhile, the time it took for a specialist to diagnose ASD depended on the TAS-20 score (rho = -0.30; p = 0.0049).
Conclusions: The results of the study indicate that the diagnosis of ASD is still a significant problem both in Poland and in the world. The long time needed to obtain the correct diagnosis is a common problem. Furthermore delaying the correct diagnosis has a significant negative impact on function, health and prognosis in patients with ASD in many contexts. Inter allia in the analysed group it was responsible for a significant increase in risk of suicidal ideations.

Reevaluating Gait Alterations in Catatonia with 3D Optical Marker-less Motion Tracking – Are gait alterations clinically overestimated?

D. C. Akkoc Altinok[1]*, K. Ohl[1], S. Volkmer[1], G. Brandt[1], S. Fritze[1] and D. Hirjak[1,2]

[1]Central Institute of Mental Health, Medical Faculty Mannheim, University of Heidelberg and [2]German Centre for Mental Health (DZPG), partner site , Mannheim, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.454

Introduction: The 3-dimensional (3D) marker-less motion capturing (MoCap) systems are an emerging technique in movement analysis. Recent studies have shown that such MoCap assessment have great potential for accurate and objective assessment of motor alterations in psychiatric patients. Gait as a fundamental gross motor function is the final motor outputs of a complex network integrating sensorimotor systems, cognitive and affective stimuli. Understanding gait alterations in catatonia patients can provide insights into their sensorimotor dysfunction and help in diagnosis and treatment in future.
Objectives: The primary objective of this study is identifying gait alterations using a 3D optical marker-less MoCap system in catatonia patients (CAT) compared to non-catatonia controls (Non-CAT). We hypothesize that there will be significant reduction in the spatiotemporal parameters of gait, such as speed, stride width, stride length, step length, and cadence as well as increased gait instability in CAT group. Moreover, these alterations will be correlated with general psychomotor slowing.
Methods: In this cross-sectional study, we examined a total of 61 patients with and without catatonia diagnosis (CAT; n=22, Non-CAT; n=39) according to ICD-11. Participants were assessed with the Positive and Negative Syndrome Scale (PANSS), Northoff Catatonia Rating Scale (NCRS), the Brief Psychiatric Rating Scale (BPRS), Global Assessment of Functioning (GAF). We conducted clinical psychomotor examination with the Heidelberger Neurological Soft Sign Scale (NSS), Salpêtrière Retardation Rating Scale (SRRS) and Unified Parkinson Disease Rating Scale (UPDRS). Gait analysis were performed using a marker-less MoCap system with 8 cameras (Qualisys, Goeteborg, Sweden). Participants walked on a marked path (18 m) with a self-selected tempo during the experiment. The spatiotemporal parameters (STP) of gait were obtained automatically through Theia Software.
Results: The two groups did not differ in age, sex, or BMI. The CAT group showed higher scores in PANNS, BPRS, NCRS and GAF ($p< 0,05$). We found a statistically significant difference in clinical psychomotor parameters in NSS, SAS and UPDRS between the two groups ($p <0,05$) and more specifically in gait subdomain of each scale. No differences were found in any of STP of gait or gait instability measurements after controlling for covariates (age, sex, BMI and medication).

Image 1:

Example of experimental set-up of marker-less 3D MoCap

Conclusions: This study exhibit a significant difference between the results of clinical psychomotor assessments and objective gait analysis through marker-less MoCap. This discrepancy suggests a potential overestimation of gait alterations in clinical evaluations. The findings underscore the importance of integrating advanced 3D MoCap technologies into the psychiatric assessment to enhance our understanding of gait alterations in mental disorders.

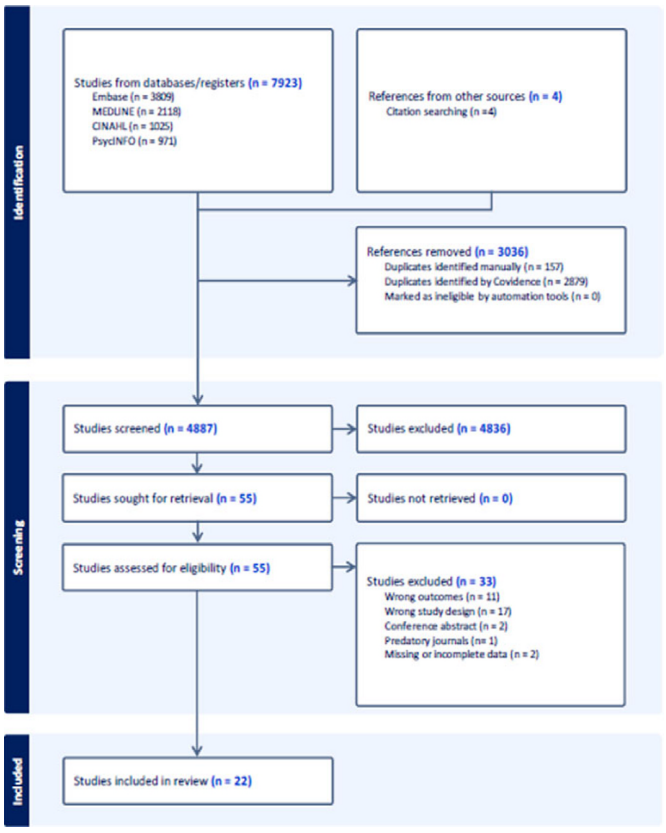
*Corresponding author.

doi: 10.1192/j.eurpsy.2025.455



Introduction: Given the increasing rates of antipsychotic use in multiple psychiatric conditions, greater attention to the assessment, monitoring and documentation of their side effects is warranted. While significant attention has been provided to metabolic side effect monitoring, comparatively little is known about how clinicians screen for, document and monitor their motor side effects (i.e. parkinsonism, akathisia, dystonia and tardive dyskinesia (TD), collectively "extrapyramidal symptoms" or EPS).

Objectives: This review aims to systematically assess the literature for insights into current trends in EPS monitoring practices within various mental health settings globally.

Methods: In line with our preregistered protocol (PROSPERO: CRD42023482372), we systematically searched the OVID Medline, PubMed, Embase, CINAHL and PsycINFO databases for studies published from 1998 to present day. Figure 1 shows a detailed flowchart of the selection process. Included studies were assessed for quality using a modified version of the Quality Improvement Minimum Criteria Set (QI-MQCS) and findings summarized using narrative synthesis. All stages of the review process are reported in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines.

Results: A total of 22 studies met our inclusion criteria. Studies occurred in varied settings and employed a range of study designs. The APA and NICE guidelines were most commonly used to guide practice. Baseline monitoring rates in adult settings ranged from 0 to 54%, and 3.7 to 100% in child & adolescent settings. In studies reassessing EPS monitoring rates following practice improvement initiatives, virtually all demonstrated benefits. Screening processes and instruments varied, ranging from standardized rating scales (such as the AIMS for TD screening) to locally developed tools. In some studies, no structured tool was identified. Monitoring rates were higher when structured processes and tools were used.

Image 1:

Conclusions: This review demonstrates significant heterogeneity in clinical practice for the screening, documentation, and monitoring of EPS in patients prescribed antipsychotic medication in mental health settings globally. Adherence to existing guidelines was found to be poor in most settings, with practice improvements observed in virtually all settings where quality improvement initiatives were implemented. The best improvements were seen to occur after services introduced structured EPS screening tools with regular education on their use.

Protocol for the Management of Metabolic and Cardiovascular Risk in Psychiatric Inpatients

J. Barreira[1]*, C. Rodrigues[2], D. Barbosa[3] and S. Macedo[1]

[1]Psychiatry and Mental Health; [2]Endocrinology and Nutrition and [3]Internal Medicine, Unidade Local de Saúde do Tâmega e Sousa, Porto, Portugal

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.456

Introduction: Psychiatric patients, especially those with psychotic disorders, face an increased metabolic and cardiovascular risk, which ultimately leads to higher mortality from cardiovascular disease and reduced life expectancy. This is due to a multitude of risk factors, including those related to the course of the mental illness, lifestyle, socioeconomic and cultural circumstances, and the use of certain medications, such as atypical antipsychotics. This underscores the need for structured interventions during hospitalization to identify and manage these risks. Non-pharmacological interventions, such as physical activity and dietary education, have shown to be beneficial in managing weight and improving cardiovascular health. Pharmacological treatments, particularly the use of metformin and aripiprazol, have demonstrated efficacy in reducing metabolic disturbances such as weight gain, dyslipidemia, and hyperglycemia. The implementation of structured protocols to mitigate metabolic risk in psychiatric inpatients is recommended.
Objectives: The main goal of the protocol is to guide the assessment, diagnosis, and therapeutic management of metabolic and cardiovascular risk factors in psychiatric inpatients. It also aims to guide the follow-up of these patients after discharge and coordination with other medical specialties.
Methods: The protocol was developed in an interdisciplinary manner, involving the specialties of Psychiatry, Endocrinology, and Internal Medicine, and is based on recent guidelines and recommendations from other countries on this matter. The protocol was also adapted to the current conditions of the psychiatric inpatient setting.
Results: The protocol involves a thorough clinical evaluation, including medical history, physical examination, and extensive laboratory analysis to identify comorbidities. Cardiovascular risk is calculated using the SCORE2, PRIMROSE and QRISK3 models. Non-pharmacological interventions include physical activity programs and nutritional counseling, while pharmacological interventions involve adjusting antipsychotic medications, selecting antipsychotics with more favourable metabolic profiles, and the adjuvant use of medications like metformin, aripiprazol, and topiramate. These evaluations are conducted at regular intervals, including post-discharge, to assess the efficacy of these interventions.
Conclusions: Psychiatric inpatients, especially those on atypical antipsychotics, face significant metabolic and cardiovascular risks. A comprehensive assessment of risk factors and early intervention during hospitalization, combining lifestyle modifications and pharmacological treatments, can significantly reduce these risks and improve patient outcomes. Continued monitoring and coordination with outpatient services post-discharge are essential for sustained management of these health risks.

Inter-rater reliability of psychiatric diagnosis: a systematic review and metanalysis

C. L. Di Forti[1,2*], D. Liccione[1] and C. Scarpazza[3]

[1]Department of Brain and Behavioral Sciences, University of Study of Pavia, Pavia; [2]Department of Mental Health and Addiction, ASST Santi Paolo e Carlo, Milano and [3]Department of General Psychology, University of Study of Padova, Padova, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.457

Introduction: Psychiatric diagnosis plays a key rol in the mental health care. One of the critical factors that influence the diagnostic process is inter-rater reliability, the degree to which different raters agree on the diagnosis when assessing the same patient. Despite the availability of standardized diagnostic manuals, variability in psychiatric diagnoses persists. The assessment of inter-rater reliability involves calculating statistical measures which quantify the level of agreement between raters beyond what would be expected by chance. Improving inter-rater reliability in psychiatric diagnoses is necessary for optimizing both patient care and research quality in mental health.
Objectives: Assess inter-rater reliability across main psychiatric disorders and identify the sources of variability.
Methods: This study was performed according to the PRISMA guidelines and a total of ninety-three studies were included. Regarding inclusion criteria, (1) the articles had to focus on inter-rater reliability, (2) study participants had to have an average age greater than 18 years, and (3) the reported diagnoses had to refer to a diagnostic manual. Quality scores were assessed for all included studies (Armijo-Olivo S *et al.* J Eval Clin Pract. 2012; 18 12-8). Seven different meta-analysis were conducted, one for each psychiatric diagnosis detected. The heterogeneity between studies was quantified using Cochran's *Q* and I^2. Funnel plots was analyzed to assess the possible influence of publication and location biases (Higgins&Green. BMJ. 2011;343). To account for publication bias, the Eggers' test and the Fail-Safe Number31 was applied.
Results: Psychotic disorder: (k=0.70; 95% CI: 0.66-0.75) (I^2=97%).
Anxiety Disorders: (k=0.65; 95% CI: 0.60-0.70) (I^2=91%).
Obsessive-Compulsive Disorder (OCD): (k=0.73; 95% CI: 0.64-0.82) (I^2=76%)
PTSD: (k=0.60; 95% CI: 0.52-0.66) (I^2 =84%).
DCA: (k=0.73; 95% CI: 0.67-0.79) (I^2 =76%).
Personality disorder (PD): two different meta-analysis were conducted because many studies used Intraclass Correlation Coefficient (ICC) as a value to express inter-rater agreement. [k=0.65 (95% CI: 0.59, 0.7)] (I^2= 96%) (ICC=0.85; 95% CI: 0.82-0.87) (I^2 = 66%).

Image 1:

Conclusions: The lower Kappa for **schizoaffective disorder** (Kappa < 0.7) compared to other psychiatric disorders underscores the diagnostic challenges posed by this category, given its overlapping symptoms with both mood and psychotic disorders. As regards personality disorder, **antisocial and borderline PD** showed highest agreement potentially due to its well-defined diagnostic criteria. The lowest agreement (k=0.60) of **PTSD** emphasizes the variability of his clinical presentation. In conclusion, studies show variability across disorders, highlighting the need for further research to improve diagnostic accurac (Regier *et al.* Am J Psychiatry. 2009;166 645-50) thereby enhancing clinical and research outcomes.

Multidimensional Study of the Attitude towards Euthanasia of Older Adults with Mixed Anxiety-Depressive Disorder

L. Fonseca[1,2*], G. Rêgo[1] and R. Nunes[1]

[1]Bioethics, Faculty of Medicine, University of Porto, Porto and [2]Psychiatry, Senhora da Oliveira Hospital, Guimarães, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.458

Introduction: Euthanasia is an ancient theme that, especially since individual autonomy became the health paradigm in contemporary societies, has sparked profound reflections and declared dissensions between different socio-ideological quadrants. The experience of the countries where it is decriminalised shows a tendency to broaden the clinical, age and legal assumptions for its access. Older adults with psychiatric disease, a clinically and socially idiosyncratic group, where physiological weaknesses and social losses accumulate, and the chronological proximity to death becomes progressively more self-aware, are a group of particular concern.
Objectives: Our research aimed to reflect on the Constitutional feasibility of Euthanasia in Portugal, make available a validated psychometric instrument to assess attitudes towards euthanasia and do a multidimensional study of the attitudes towards euthanasia of older adult patients with mixed anxiety-depressive disorder.
Methods: The field research study applied a paper questionnaire composed of a sociodemographic section and a battery of scales (to assess depression, anxiety, cognitive performance, suicide risk, therapeutic adhesion, functionality, loneliness, attitude towards euthanasia, decision pattern, personality, empathy and health status) in the Psychogeriatric Unity of Senhora da Oliveira Hospital in Portugal. The sample was collected by convenience. The multidimensional study included 114 patients and 25 controls of the same age. Six months later, a reassessment was conducted. Patients and controls were compared using descriptive statistics and a multiple-regression model.
Results: The Constitution of the Portuguese Republic does not prohibit medically assisted death. The results support the validated scale's usefulness and validity. Eighty-one point six per cent of patients had four or fewer years of schooling. Contrary to controls, they presented mild depressive and anxiety symptoms, loneliness feelings, worse cognitive performance, a more fragile personality, higher personal distress and a poorer health state. No statistically significant differences were found between controls and patients regarding their attitudes towards euthanasia. Patients more favourable to euthanasia had higher empathic concern, conscientiousness and fantasy and lower personal distress.
Conclusions: When addressing euthanasia in older adult patients with mixed anxiety and depressive disorder, it is crucial to ensure they are fully self-determinate and that all the necessary treatment and support are available. It may not be the case when the educational level is low and mild disease persists, significantly affecting their well-being and cognitive performance.

Recruiting hard-to-reach populations for surveys: A case of people with schizophrenia and coexisting diabetes

S. T. Rønne[1,2*], B. Cleal[3], P. H. Gæde[4,5], S. M. Arnfred[2,6] and R. Jørgensen[7,8]

[1]Research Unit of Psychiatry West, Region Zealand, Slagelse; [2]Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen; [3]Steno Diabetes Center Copenhagen, Copenhagen University Hospital, Copenhagen; [4]Department of Cardiology and Endocrinology, Slagelse Hospital, Slagelse; [5]Department of Regional Health Research, University of Southern Denmark, Odense; [6]Psychiatric Research Unit, Region Zealand, Slagelse; [7]Unit for Psychiatric Research, Aalborg University Hospital and [8]Department of Clinical Medicine, Aalborg University , Aalborg, Denmark
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.459

Introduction: In research, recruitment challenges are common and lead to delays and reduce sample size and power. People with schizophrenia are often described as hard to reach and retain in research, and in particular, studies targeting people with chronic comorbidities such as diabetes, meet difficulties related to recruitment.
Objectives: This study aims to describe challenges and strategies to recruitment of Danish adults with schizophrenia and type 2 diabetes to a cross-sectional survey study about psychosocial health and support.
Methods: The recruitment process was tracked in a register where all relevant information was synthesized systematically. This included information on how eligible participants were identified and invited for the study and reasons for declining. Two recruitment strategies were applied for recruiting participants to complete a questionnaire: 1) Through mental health professionals in psychiatric outpatient clinics in Region Zealand, Denmark, and 2) Through phone calls to eligible participants. Descriptive analyses of the recruitment data were conducted.
Results: Three types of challenges were found and described: 1) Identifying eligible participants, 2) Challenges with having mental health professionals to recruit, and 3) Participants' lack of ability to complete a questionnaire. The challenges were met by several practical approaches: 1) Identifying eligible participants though

electronic health records and medication types, 2) Inviting participants through phone calls, and 3) Letting participants receiving help for completing the questionnaire from a care coordinator, family/friend or researcher when needed. Approximately 15% of all eligible participants declined to take part, which indicate high willingness to participate.
Conclusions: Exploring different types of challenges was important for understanding the actual difficulties in recruitment, for using approaches to meet the challenges, and for detecting the high willingness to take part.

The Black Box warning: Exploring the ethical considerations and mitigating medicolegal risk in prescribing antidepressants to young adults

P. Thiagayson

Institute of Mental Health, Singapore, Singapore
doi: 10.1192/j.eurpsy.2025.460

Introduction: Since October 2004, antidepressants have had a black-box warning indicating that they are associated with an increased risk of suicidal thinking, feeling, and behavior in children and adolescents. On 2nd May 2007, the United States Food and Drug Administration ordered that all antidepressant medications carry an expanded black-box warning stating an increased risk of suicidal symptoms in young adults aged 18 – 24.
The initiation of antidepressants in the young adult population present unique patient safety considerations and medicolegal risks for physicians. Unlike the triadic doctor-parent-patient relationship in a child or adolescent patient, the doctor-patient realtionship in a young adult is a dyadic one. Hence, enlisting the help of a trusted adult to supervise the young person who has been newly initiated on antidepressants is more challenging.
Objectives: In this poster, we explore the unique ethical considerations in initiating antidepressants in the young adult population and the steps clinicians may take to mitigate their medicolegal risk in treating this population. The ethical considerations of autonomy, beneficence and non-maleficence are analysed. The measures an individual clinician may take in clinical decision-making and follow-up to mitigate medicolegal risk are also discussed.
Methods: A literature search was conducted to determine the clinical considerations and prescription patterns in prescribing antidepressants to young adults. The legislation surrounding medication prescription in major jurisdictions were explored. Current literature on medicolegal risk management was studied to come up with recommendations on mitigating medicolegal risk when initiating antidepresants in young adults.
Results: Initiating antidepressants in a young adult is a collaboratively undertaken medical decision. A thorough evaluation is required to determine if antidepressant initiation is warranted. Young adults initiated on antidepressants must be closely monitored for increased suicidality. The clinician should offer to psychoeducate a member of the young adult's support network on his diagnosis and treatment, and apprise this person of the black box warning. . If there are imminent grave risks to the young person or others, confidentiality may have to be broken. Clear detailed documentation of the clinical considerations and discussion with the young person is essential.
Conclusions: Initiating antidepressants in young adults presents clinicians with unique patient safety and medicoleagl risk concerns. Steps in clinical decision-making and follow-up may be undertaken by clinicians to mitigate this risk.

Neuropathic Pains in the Age of Post-COVID-19-Vaccination

Y. I. Cao

Founder, Scientifique Global Limited, Hong Kong, Hong Kong
doi: 10.1192/j.eurpsy.2025.461

Introduction: Mainstream literature classifies SARS-CoV-2 positive-sensed single-stranded RNA (ssRNA), and only a few literature mentioned the method being Reverse Transcription–Polymerase Chain Reaction -- one limited to ssRNA studies without method improvement of RNA interference (Wang *et al.* BMC Bio 2018; 18). Studies found the 3'-to-5' exoribonuclease activity within CoV nonstructural protein 14 (NSP14) critical for CoV high-fidelity replication (Smith & Denison, PLoS Pathog 2013; 9 e1003760), and NSP15 a distinctive endoribonuclease able to cleave both ss- and double-stranded RNA (dsRNA) effectively (Frazier *et al.* NA Res 2022; 50 8290-8301). While MERS-CoV inhibit oligoadenylate synthetase–ribonuclease L, protein kinase R, and interferon (IFN), CoV-2 activates the former two and induces minimal levels of IFN (Li *et al.* PNAS 2021; 118 e2022643118), corroborating with S2 protein's homogeneity with HIV gp41 (Zhang & Yap JMS: THEOCHEM 2004; 677 73-76) with differentiated impacts on macrophage activities via interleukin 6 (Ascierto *et al.* JIC 2021; 9). **Image 1** indicates the post-vaccination pericarditis is caused by negative charge interference during depolarization in NCT05711810.
Objectives: Primary objective of advancing treatment designs followed the fixed effect metaanalysis model and gathered relevant data (Nikolakopoulou *et al.* EBMH 2014; 17 64). Secondary objective is to compare effects between presynaptic and postsynaptic treatment efficacies in order to determine infection depth for post-COVID-19-vaccination neuropathic pain to appear, and adverse events (AEs) are collected for random effects metaanalysis. Tertiary objective is to weigh the evidences whether COVID-19 is ssRNA or dsRNA.
Methods: With the framework and paradigm of sebaceous immunobiology, the pathway bypassing blood-brain barrier is found with steroidogenesis (Pachankis JP 2023; 26 615; Pachankis GJMR 2023; 23C 5-11). NCT05839236 and NCT06357104 trials' metaanalysis are illustrated in **image 2** with the observational protocol NCT06107348 in **image 3**.
Results: Sebaceous (purpura and ecchymoses) AEs appeared with postsynaptic treatments with valproate, and comparatively, presynaptic treatments with gabapentin afterwards attenuated them. Presynaptic treatments of gabapentin shows superiority by the equivalence tests on neuropathic pains' attenuation in duration

and intensities. The considerations of Ca^{2+} channel inhibition by the adoption of gabapentin in the proton-coupled electron transport chain are consistent with the electrocardiogram indications of negative charge interference on cardiac activities.

Image 1:

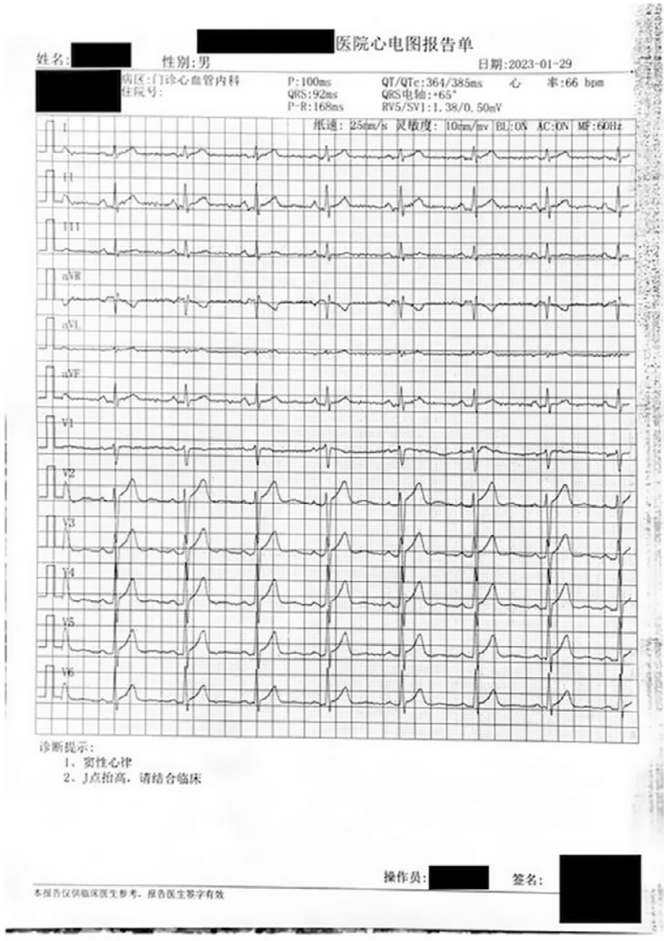

Image 2:

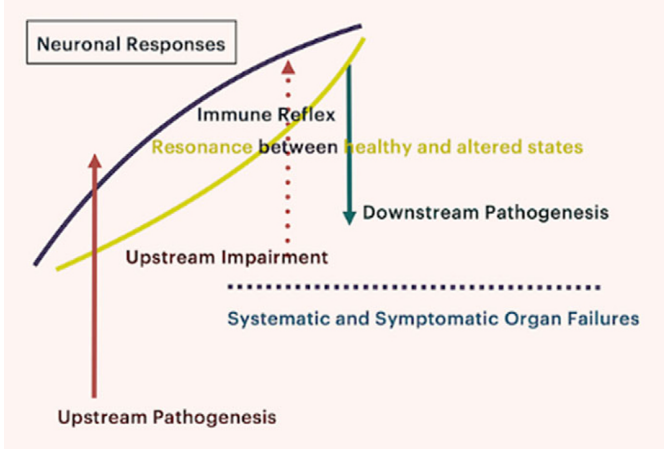

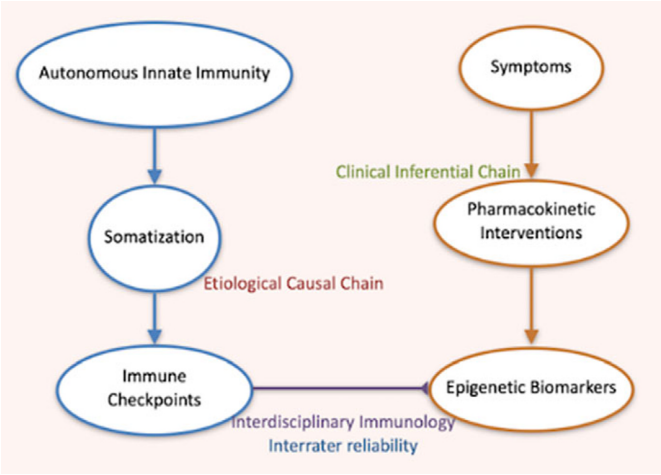

Image 3:

Conclusions: Migraine AEs in NCT05711810 trial is the neuropathic pain resulted from immune activation with initial treatment. Infection depth of neuropathic pains from COVID-19 post-vaccination symptoms is extendable to the presynaptic vesicles with impacts to macrophage activities. Indirect evidences support that SARS-CoV-2 is negative-sensed dsRNA (Pachankis JCMI 2023; 6 1-4).

Conspiracy thinking, belief in false information about COVID-19 and the severity of anxiety and depression symptoms in Polish and Spanish respondents in the final phase of the COVID-19 pandemic - preliminary report from a comparative study

P. Dębski[1,2]*, A. Cetnarowska[3], W. Madejczyk[4], E. M. Benito[3,5], M. Piegza[1], J. Smolarczyk[6] and J. Blanch[7,8]

[1]Department of Psychiatry, Medical University of Silesia, Tarnowskie Góry; [2]Institute of Psychology, Humanitas University, Sosnowiec, Poland; [3]Department of Psychiatry, Hospital Universitari de Santa Maria, Lleida, Spain; [4]Student Scientific Association, Medical University of Silesia, Tarnowskie Góry, Poland; [5]Faculty of Education, Psychology and Social Work, University of Lleida, Lleida, Spain; [6]Department of Psychoprophylaxis, Medical University of Silesia, Tarnowskie Góry, Poland; [7]Director of Mental Health and Addiction Services, Hospital Universitari de Santa Maria de Lleida, Lleida and [8]CIBERSAM, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.462

Introduction: Conspiracy thinking refers to the tendency to accept explanations about reality that are different from those that are most rational or best proven. This trend became a significant threat during the COVID-19 pandemic, as belief in false information about COVID-19 was an important factor inhibiting preventive

actions. The tendency to think conspiratorially has also been associated with the severity of some psychopathological symptoms, such as anxiety and depressive symptoms.
Objectives: The aim of the study was to assess the differences in general and COVID-19 conspiracy thinking between Polish and Spanish respondents, as well as the relationship between conspiracy thinking and the severity of anxiety and depression symptoms.
Methods: 192 Polish citizens (average age of 39.7 ± 8.61 years; women: 151, men: 41) and 190 Spanish citizens (average age of 48.3 ± 10.03 years; women: 139, men: 51) were recruted. The GCBS (Brotheron, et al.), the COVID-19 CBS (Dębski, et al.) and the HADS (Zigmond & Snaith) tools were used. The Shapiro-Wilk test, the Mann-Whitney U test and Spearman's correlation coefficient were implemented.
Results: In Spain, the highest average score in terms of conspiracy thinking about COVID-19 was obtained by the statement: "Governments deliberately spread false information about COVID-19 in order to conceal the actual state of the pandemic" (mean = 2.784), while in Poland this statement was: "SARS-CoV-2 tests are unreliable, they may be positive in the case of infection with another virus" (mean = 2.912). Spanish citizens obtained significantly higher scores than Poles on the Malevolent global conspiracies scale (median 9 vs 8, p=0.024), as well as in two false beliefs about COVID-19: "Wearing face masks causes oxygen deficiency…" (median 3 vs 2, p=0.000) and "There is a drug that can effectively cure COVID-19 patients, but information about it is confidential…" (median 3 vs 1.5, p =0.026). Among Polish citizens, the belief: "Health workers receive financial benefits for diagnosing COVID-19…" was higher (median 2 vs. 1, p=0.000). In the Spanish group, most of the GCBS subscales correlated positively with the anxiety and depression symptoms. COVID-19 CBS also correlated with anxiety. In the Polish group positive correlations were noted between two GCBS scales and the severity of depression symptoms. There were no significant associations between GCBS and COVID-19 CBS with the anxiety symptoms in that group.
Conclusions: The group studied in Spain showed a significantly higher intensity of conspiracy beliefs in more issues than the group studied in Poland. At the same time, conspiracy thinking in the Spanish group showed more pronounced relationships with the severity of anxiety and depression symptoms than in the Polish group.

Proactive Model of Remote Interaction for Treating Post-COVID Anxiety and Depression in the Context of War in Ukraine

O. O. Khaustova[1]*, A. O. Burdeinyi[1] and O. S. Chaban[2]

[1]Department of Medical Psychology- Psychosomatic Medicine and Psychotherapy and [2]Bogomolets National Medical University, Kyiv, Ukraine
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.463

Introduction: Remote interaction offers new opportunities for medical-psychological rehabilitation, providing access when in-person consultations are limited. The proactive model of psychosomatic medicine, focusing on prevention and can to enable continuous monitoring and active patient engagement, crucial for those affected by post-COVID syndrome and war.
Objectives: Analyze the effectiveness of a medical-psychological rehabilitation program for anxiety and depressive post-COVID disorders, as well as post-traumatic symptoms resulting from war, in the context of remote interaction.
Methods: The study sample consisted of 240 individuals with anxiety and depressive post-COVID disorders. The tools used in the study included the PHQ-9, GAD-7, and PCL-5.
Results: By day 63, according to the PHQ-9, depression in the study group decreased to 6.942±5.073, while in the control group it remained at 15.567±6.540 ($p < 0.001$; $t = 11.437$). According to the GAD-7, anxiety reduced to 3.991±3.589 in the study group, whereas in the control group it remained higher at 12.966±3.980 ($p < 0.001$; $t = 18.355$). According to the PCL-5, PTSD symptoms decreased to 13.295±8.727 in the study group, while in the control group they remained high at 29.177±13.541 ($p < 0.001$; $t = 10.836$).
Conclusions: The study results indicate that the medical-psychological rehabilitation program, delivered through remote interaction, effectively reduces symptoms of depression, anxiety, and post-traumatic stress in individuals with post-COVID disorders amid wartime conditions.

Insomnia during the COVID-19 pandemic: Evidence from a Longitudinal Cohort study in Singapore

P. Satghare[1]*, E. Abdin[1], S. Shafie[1], B. Tan[1] and M. Subramaniam[1]

[1]Research, Institute of mental health, Singapore, Singapore
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.464

Introduction: Since the outbreak of Coronavirus Disease 2019 (COVID-19) pandemic, sleep and mental health of the population have been disrupted worldwide. Predisposing, precipitating, and perpetuating factors of insomnia may signify shared mechanisms that relate insomnia symptoms to psychiatric disorders during stressful periods like pandemic. However, long term repercussions of COVID-19 pandemic on sleep features such as insomnia, and psychological health remains poorly elucidated even after the alleviation of the pandemic measures.
Objectives: The current study aims to identify the longitudinal trajectory of insomnia, in terms of prevalence and associated risk factors, during and post COVID-19 pandemic era among the general population of Singapore.
Methods: Current study consists of longitudinal online and in person surveys involving two-point assessments-Phase1 (during pandemic) from May 2020-June 2021 and Phase2 (post pandemic) from October 2023-August 2024. Singapore residents aged 21 years and above, fluent in English, Chinese or Malay language participated in the study. Participants answered an interviewer-administered questionnaire across both timepoints, including Socio-Demographic information, Insomnia Severity Index, Generalised Anxiety Disorder-7, Physical Health Questionnaire, Depression Anxiety Stress Scales and Covid-19 related stressors-Exposure to Covid-19, current and future perceived risk of infection.
Results: 597 participants completed both assessments at phase1 and phase2. The prevalence of insomnia increased from 8.83% in

phase2 as compared to 8.24% in phase1 (p<0.00). Those aged 50 years and above (vs 21-34 years) (p<0.02), highest educational attainment of primary school (vs University) (p<0.05), being economically inactive (vs employed) (p< 0.01), having mild levels of anxiety (p<0.007) and having severe levels of depression, anxiety or, stress (p<0.005) was seen to be significantly associated with insomnia.
Conclusions: Insomnia prevalence rose from 8.24% in phase1 to 8.83% in phase2 and was significantly associated with anxiety disorder, psychological distress, and perceived stress among Singapore residents in both phases. These findings could be ascribed to the failure in re-establishment of pre-COVID-19 pandemic norms, social situations and working dynamics that might have led to sleep curtailment and insomnia. Study findings can be utilised to design effective targeted interventions like cognitive behavioural therapy, therapist assisted relaxation and meditation programs to improve sleep and reduce psychological distress. Mentioned interventions can be delivered via smartphone applications enabling easy access, monitoring, delivery, and utilization by the vulnerable groups.

Investigating amygdala habituation in major depressive disorder: an fMRI study in UK Biobank

L. Fortaner-Uyà[1,2*], C. Verga[2], S. Cademartiri[1], E. Tassi[3,4], P. Brambilla[3], E. Maggioni[4], C. Fabbri[5], F. Benedetti[1,2] and B. Vai[1,2]

[1]University Vita-Salute San Raffaele; [2]Division of Neuroscience, IRCCS San Raffaele Hospital, Psychiatry and Clinical Psychobiology Unit; [3]Department of Neurosciences and Mental Health, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico; [4]Department of Electronics - Information and Bioengineering, Politecnico di Milano, Milan and [5]Department of Biomedical and Neuromotor Sciences, University of Bologna, Bologna, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.465

Introduction: Major depressive disorder (MDD) is a severe psychiatric condition with a high risk of suicide. Research on MDD and suicidality has identified structural and functional abnormalities in the cortico-limbic network as candidate biomarkers, but little is known about the temporal dynamics of these brain regions. Recently, abnormal amygdala habituation to emotional stimuli has been highlighted as a reliable fMRI phenotype linked to emotional dysregulation and increased suicide risk.
Objectives: Our study aimed to assess amygdala habituation to emotional stimuli in MDD and explore differences between suicide attempters (SA) and non-attempters (nSA). Additionally, we examined the relationship between amygdala habituation and depressive symptoms.
Methods: 414 MDD patients (239 SA, 175 nSA) selected from the UK Biobank underwent fMRI during a block-designed emotion processing task, including faces and shapes conditions. We obtained bilateral amygdala activation for each block using FSL. Habituation was quantified using two methods: the regression approach (REG) and First minus Last block (FmL). One sample T-tests were used to investigate whether habituation rates significantly differed from zero. Group differences were analysed using Mann-Whitney U-tests. Generalized linear models (GLM) were applied to examine relationships between habituation and depression severity, controlling for age, sex, group (SA vs. nSA), and handedness.
Results: In both MDD and SA groups, no significant habituation was observed for either emotional or non-emotional stimuli (p_{FDR}>.05). However, the nSA group showed significantly positive habituation rates for left amygdala in both conditions and for right amygdala in faces condition using REG (p_{FDR}<.05), suggesting a possible sensitization process. Moreover, nSA showed significantly higher habituation rates than SA in all conditions with REG (p_{FDR}<.01). GLM analyses revealed no significant associations with depression severity.
Conclusions: Our results suggest that MDD is characterized by a lack of amygdala habituation to emotional stimuli, potentially offering new insights into its pathophysiology. This biomarker may help in developing novel therapeutic strategies targeting the amygdala and its regulation within the cortico-limbic system.
Fundings: The current study was supported by the Italian Ministry of Health, GR-2019-12370616.

Is there a risk of addiction to ketamine during the treatment of depression? A systematic review of available literature

G. Ingrosso[1,2*], A. Cleare[1] and M. Juruena[1]

[1]Institute of Psychiatry, Psychology and Neuroscience, King's College London, Centre for Affective Disorders, London, United Kingdom and [2]Department of Health Sciences, University of Milan, Milan, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.466

Introduction: Depression is a leading cause of disability globally, and while conventional treatments, such as antidepressants and psychological therapy, benefit many patients, a significant proportion fail to achieve symptom relief. Ketamine has demonstrated both rapid and sustained efficacy in treating depression, especially in treatment-resistant cases. However, concerns regarding the addictive potential of ketamine during long-term depression treatment persist among clinicians.
Objectives: The review aimed to assess the prevalence of addiction phenomena associated with ketamine treatment of depression in adult populations.
Methods: The review followed PRISMA guidelines and was preregistered on PROSPERO (CD42023435468). A comprehensive search was conducted in Medline, Embase, PsycInfo and Global Health databases, with additional relevant studies identified through reference lists. Data extraction and study selection were performed by two independent reviewers. Risk of bias was assessed using appropriate tools based on study design.
Results: Sixteen studies were included, comprising six randomised controlled trials, three single-arm open-label studies, one retrospective study, three case series and three case reports, for a total of 2174 patients. The studies employed various routes of administration, including intravenous, intramuscular, intranasal, oral and sublingual. Ketamine was administered in the racemic

form, except for the studies that utilised intranasal esketamine. Four patients were reported to exhibit clear signs of tolerance to the antidepressant effects of ketamine or dependence on the drug, while the majority did not. Additionally, papers discussing addiction phenomena in studies that did not meet the inclusion criteria are also reviewed.
Conclusions: Despite the heterogeneity in study designs and outcome assessment methods, the review underscores the relative safety of ketamine treatment for adult patients with depression, emphasising the importance of medically supervised administration, vigilant monitoring and judicious dosing. Future long-term studies employing quantitative scales to assess dependence phenomena could contribute to strengthen the evidence for a safe and effective use of ketamine in the treatment of depression.

Heterogeneity in depression treatment trajectories and associated social factors: a longitudinal cohort study in older adults in Denmark

K. Ishtiak-Ahmed[1,2], C. Rohde[1,2], O. Köhler-Forsberg[2,3], K. S. Christensen[4,5] and C. Gasse[1,2,3]*

[1]Department of Affective Disorders, Aarhus University Hospital Psychiatry; [2]Department of Clinical Medicine, Aarhus University; [3]Psychosis Research Unit, Aarhus University Hospital Psychiatry; [4]Research Unit for General Practice and [5]Department of Public Health, Aarhus University, Aarhus N, Denmark
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.467

Introduction: While depression trajectories have been extensively studied in recent decades, research has predominantly focused on younger and middle-aged individuals, often overlooking vulnerable older patients. Classifying patients based on treatment trajectories may enhance personalized care efforts and long-term treatment management for older adults.
Objectives: This study investigates the varying patterns of depression treatment trajectories and examines the influence of social factors on these trajectories in older adults initiating first-time depression treatment over a three-year period.
Methods: We conducted a nationwide cohort study using Danish registers, including all adults aged 65 and older who filled their first-time antidepressant prescriptions between 2006 and 2015 (with no prescriptions in the previous decade). Depression treatment patterns were assessed through antidepressant prescription redemptions and psychiatric hospital contacts for depression. Latent class growth modeling identified distinct treatment trajectories over the three years, while multinomial logistic regression analyzed the association between social factors and trajectory group membership.
Results: Among the 66,540 older adults included in the study (55.2% female, mean age: 77.3 years), three unique depression treatment trajectories emerged: 'brief treatment' (33.7%), where treatment ended within six months; 'gradual withdrawal' (26.5%), where treatment tapered off over two years; and 'persistent treatment' (39.8%), where treatment continued throughout the three years. Association analyses showed that female sex, living alone, and residing in less-urbanized regions were associated with higher odds of membership in the persistent treatment group. In contrast, older individuals, those who were widowed or separated, and individuals of non-Danish ethnicity were associated with lower odds of membership in the persistent treatment group.
Conclusions: This study identifies three distinct depression treatment trajectories in older adults. Social factors such as sex, household composition, place of residence, and ethnicity were associated with treatment duration and trajectories. Tailored interventions based on patient characteristics may enhance depression care for older adults, ensuring more personalized and effective treatment strategies.

Financial performance of people with affective disorders: A prospective, European-wide study

T. Jiang[1]*, G. Gaastra[1] and J. Koerts

Department of Clinical and Developmental Neuropsychology, University of Groningen, Groningen, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.468

Introduction: Financial capability, which encompasses both financial competence and financial performance, is a key requirement for an autonomous and independent life. However, individuals with psychiatric disorders often report difficulties with financial capability and financial stress.
Objectives: The current study aims to disclose the impact of affective disorders (AD) on financial performance using prospective data from wave 8 and wave 9 of the Survey of Health, Retirement and Ageing in Europe (SHARE).
Methods: The SHARE project includes individuals born on or before 1971 or households with at least one member meeting this age criterion. During each wave, participants reported whether they received one of 17 diagnoses, including "affective or emotional disorders, including anxiety, nervous or psychiatric problems". Furthermore, monthly household net income and whether participants experienced difficulties in managing money, challenges in making ends meet, and their debt situation were recorded. The differences between the AD and a control group (i.e., participants without affective or neurological conditions) on monthly household net income and the three financial performances were examined for both waves. Logistic regression analyses were performed to analyze whether an AD diagnosis predicted financial performances in wave 8 and wave 9.
Results: 2,645 individuals reported an AD diagnosis in wave 8, and 47,068 were classified as controls. In wave 9, 3,574 individuals indicated having an AD diagnosis and 60,902 were classified as controls. In both waves, individuals with AD received a lower monthly household net income and reported more difficulties across all three financial performances relative to controls.

Furthermore, in both waves, AD individuals reported having more debts on cars and other vehicles, debt on credit/store cards, loans, debts to relatives or friends, overdue bills, and other types of debts than controls. In wave 8, the odds of experiencing difficulties in managing money, making ends meet, and having debts were 3.61, 1.45, and 1.73 times higher, respectively, in AD individuals than in controls. A diagnosis of AD increased the likelihood of future (i.e., during wave 9) financial difficulties: 2.67, 1.38 and 1.68 times for managing money, making ends meet, and having debt, respectively.
Conclusions: Individuals with AD are more prone to experiencing impairments with both current and future financial performance and might face financial difficulties. The present study emphasizes the importance of recognizing financial difficulties in individuals with AD and offering financial assistance when necessary, especially since financial difficulties might exacerbate affective symptoms.

Clinical improvement of moderate depression with a combination of rhodiola and saffron in a non-student population: a double-blind, placebo-controlled study

P. Lemoine[1]*, C. Gal[2], E. Jacouton[2] and S. Ait Abdellah[2]

[1]Lyon University, Lyon and [2]Pileje Laboratoire, Paris, France
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.469

Introduction: A number of medicinal plants have produced noticeable results in depression treatment including, *Rhodiola rosea* and *Crocus Sativus* (saffron).
Objectives: To evaluate the efficacy and safety of a combination of rhodiola and saffron in patients with moderate depression.
Methods: Adults with moderate depression (International Classification of Diseases [ICD-10]) of moderate intensity (Hamilton Depression Score [HAM-D] ≥ 17 and ≤ 23) were recruited (n=126; 64 students, 62 non students). Patients took 2 tablets of the supplement (i.e. 308 mg rhodiola and 30 mg saffron) or a placebo daily for 6 weeks. Main criterion was the evolution of HAM-D score between Day (D) 0 and D42. Other criteria were evolution of HAM-D, Hospital Anxiety and Depression Scale (HADS)-anxiety and HADS-depression, Patient's Global Impression of Change (PGIC), Clinical Global Impression of severity and improvement (CGI-S and -I) at D0, D21 and D42, tolerability and compliance.
Results: A significant 10-point decrease in HAM-D score was observed only in the supplemented non-student population between D0 and D21 (from 18.9±1.7 to 8.6±3.4 in Supplement group *versus* 18.5±1.8 to 11.2±4.2 in Placebo group, p=0.005). At D42, a 12-point decrease was observed in the Supplement group; the difference between the two groups being marginally significant (from 18.9±1.7 to 7.1±5.0 in Supplement group versus from 18.5 ±1.8 to 8.8±4.2 in Placebo group, p=0.087). The percentage of patients with a HAM-D score reduction >75% was higher in the Supplement group (p<0.05). The HAM-D score decrease was particularly marked in patients with HADS-anxiety ≥11 at D21. The distribution of patients by severity HAM-D classes (no, mild, moderate depression) was significantly different between the two groups (p<0.05 at D21 and D42), with a greater number of patients with no or mild symptoms in the Supplement group. The remission rate (HAM-D ≤ 7) was higher in this group (p<0.05 at D21 and D42). These results by classes were also found with HADS-depression scale. Results for CGI-S and CGI-I were in favor of the Supplement group (p<0.05 at D21). These results were not observed in students. Compliance and tolerability were good.
Conclusions: As expected, the rhodiola plus saffron combination improved psychological well-being of non-student patients with moderate depression. The poor results observed in students suggest that health professionals should ascertain the real depressive state of students confronted with stressful and/or anxiety-provoking situations linked to exams, professional future or precarity. When prescribing, clinicians should not only rely on quantitative scales, but above all on their clinical feelings.

Assessment of clinical course among patients with major depressive disorder treated with sertraline: a retrospective observational real-world study

P. Purushottamahanti[1]*, C. U. Correll[2,3,4,5], K. Subramaniam[6], B. Bayan[7], N. Lipunova[8], E. O. Palmer[8], J. Yeow[9] and J. Wong[9]

[1]Global Medical Affairs, Viatris Inc., Bangalore, India; [2]Department of Psychiatry, Zucker Hillside Hospital, Northwell Health, Glen Oaks, NY; [3]Department of Psychiatry and Molecular Medicine, Zucker School of Medicine at Hofstra/Northwell, Hempstead, NY; [4]Center for Psychiatric Neuroscience, Feinstein Institute for Medical Research, Manhasset, NY, United States; [5]Department of Child and Adolescent Psychiatry, Charité Universitätsmedizin, Berlin, Germany; [6]Global Medical Affairs, Viatris Inc., Auckland, New Zealand; [7]GMARH, Viatris Inc., Bangalore, India; [8]Holmusk Technologies Inc., London, United Kingdom and [9]Holmusk Technologies Inc., Singapore, Singapore
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.470

Introduction: Major depressive disorder (MDD) is a chronic condition with recurrence rates ranging between 50-90%. MDD is also one of the leading causes of functional impairment (Moriarty AS *et al. Br J Gen Pract.* 2020 Jan 30;70(691):54-55). Therefore, clinical practice guidelines (CPGs) recommend continuing antidepressant treatment of MDD (6-24 months) beyond achieving clinical remission to prevent relapse. Sertraline, a selective serotonin reuptake inhibitor, is recommend as a first line agent by most CPGs in the management of MDD (Lam RW *et al. Can J Psychiatry.* 2024 Sep;69 (9):641-687, NICE guideline Jun 2022).
Objectives: To evaluate the effectiveness of sertraline in the long-term management of MDD in a real-world clinical practice setting.
Methods: A retrospective, observational study of real-world data assessed the clinical course in patients with MDD with or without comorbid anxiety disorders (N=713, female=526), who were prescribed sertraline. Data from >25 mental health centers in the USA from Holmusk's NeuroBlu database were used to estimate the effectiveness of sertraline in patients with moderate to severe MDD (CGI-S ≥ 4, n=556, female=414). Changes in CGI-S from baseline to months 2, 3, 6, 9 and 12 following sertraline initiation were analyzed. One point or more reduction in CGI-S was regarded

as improvement, one point or more CGI-S increase was by denoted as worsening. Stability was assumed where no CGI-S change was observed.

Results: In comparison to baseline, patients showed a general trend for improvement, regardless of the available follow-up duration **(Fig 1)**. In total, 32.7% to 41.9% patients with moderate to severe MDD showed clinically meaningful improvement across any of the time points **(Fig 2)**.

Image 1:

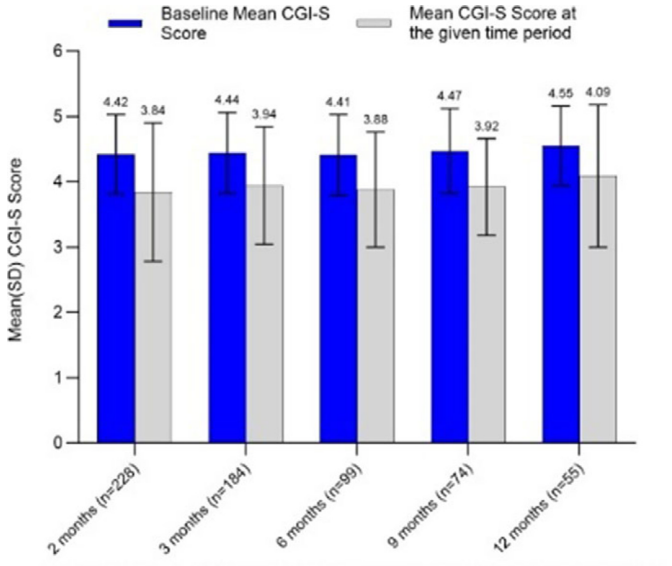

Fig 1 - Mean CGI-S at baseline and at corresponding follow-up periods

Image 2:

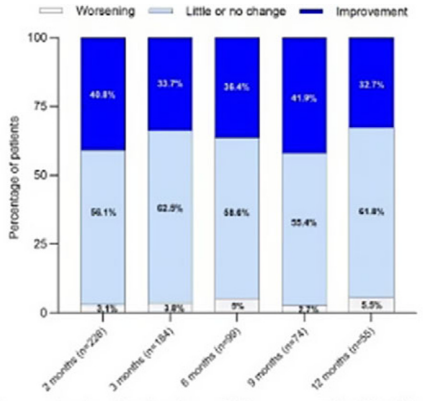

Fig 2 - CGI-S change categories when baseline and follow-up score at a defined time point were compared. Improvement: Change in CGI-S≤1; No change: Change in CGI-S=0; Worsening: Change in CGI≥1

Conclusions: The results from this retrospective analysis of health records suggest that sertraline is an effective treatment in the management of MDD in real-world clinical practice, even in the long-term.

Limitations: First, this study only assessed patients who had CGI-S recorded at baseline and at least one additional recorded at any of the pre-defined follow-up points. As a result, patients who did not have a follow-up CGI-S value or had the value recorded outside of the pre-defined follow-up points were excluded from the study. The study also did not assess detailed MDD symptom ratings. Finally, information was lacking whether patients were treated previously in other clinical setting.

Antidepressant effect of ketamine unrelated to dissociation: Results from an exploratory mediation analysis of the KET01-02 study

L. Arvastson[1]*, E. Papanastasiou[1], K. Schmid[2], A. Damyanova[1], A. Glas[1], C. Strote[1], C. Eulenburg[1], D. Gehrlach[1], K. Maiboe[1] and H. Eriksson[1]

[1]HMNC Brain Health, Munich, Germany and [2]Develco Pharma, Pratteln, Switzerland

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.471

Introduction: Current ketamine-based therapies for treatment-resistant depression (TRD) can induce dissociative symptoms. A novel oral prolonged-release ketamine formulation (KET01) results in a lower and delayed peak concentration of ketamine, and a higher concentration of the metabolites norketamine and hydroxynorketamine than after intravenous administration. KET01 has limited dissociative properties, compared to other ketamine formulations.

Objectives: To explore the relation between dissociative and antidepressant effects of KET01.

Methods: KET01-02 (EudraCT 2021-004927-34) was a randomized, double-blind phase 2 trial in outpatients with TRD comparing adjunct 120 mg (n=42) or 240 mg (n=40) oral KET01 once-daily for 3 weeks to placebo (PBO, n=40). The primary endpoint was change from baseline on the Montgomery-Åsberg Depression Rating Scale (MADRS) total score on day 21. Dissociation was assessed using the Clinician-Administered Dissociative States Scale (CADSS).

The association between CADSS scores at 7 hours after first dosing and MADRS scores on day 4 was investigated with a statistical mediation analysis. The 7-hour timepoint was selected since it coincides with the average Tmax (time-to-peak) when the highest dissociation is expected. Depression scores at the first subsequent visit (on day 4) were selected for the analysis. It was also the time point where change in MADRS score from baseline differentiated the most between KET01 and placebo with a difference of 4.32 (p=0.006) to the benefit of KET01 – based on the model used in the mediation analysis.
Results: The antidepressant effect of KET01 that was mediated through dissociation was estimated to the negligible -1.28% (CI: (-28%) – (+11%)).
Conclusions: The antidepressant effect of KET01 was achieved with minimal to no dissociation and with no significant mediation through dissociation. Our findings challenge the commonly held clinical view that some degree of dissociation is necessary to guarantee ketamine's antidepressant effect. Instead, it appears that dissociative symptoms are merely adverse events associated with certain formulations of ketamine.

Impacts of childhood trauma on postpartum depression: prospective longitudinal study

E. B. Camargo Júnior[1]*, G. G. Silva[1], M. N. D. F. Fernandes[2] and E. C. D. S. Gherardi-Donato[3]

[1]University of Rio Verde, Rio Verde; [2]Federal University of Maranhão, Imperatriz and [3]Ribeirão Preto College of Nursing, Ribeirão Preto, University of São Paulo , Ribeirão Preto, Brazil
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.472

Introduction: Women who experience childhood trauma may be at a greater risk of developing postpartum depression (PPD), which can result in significant harm to both mothers and their children. Few studies have longitudinally evaluated the effect of childhood trauma on PPD.
Objectives: This study aimed to evaluate the impact of childhood trauma on PPD among Brazilian postpartum women.
Methods: This prospective longitudinal study was conducted with 153 women evaluated at two time points: T1 (immediate postpartum) and T2 (three months postpartum). PPD symptoms were assessed using the Edinburgh Postnatal Depression Scale (EPDS) and childhood trauma was assessed using the Childhood Trauma Questionnaire (CTQ). To verify the differences in PPD scores in the periods assessed and in relation to childhood trauma, generalized estimating equations (GEE) were used. EPDS scores were categorized with values ≥10 defined as the presence of PPD. Multinomial logistic regression analyses were performed to evaluate the influence of trauma on PPD risk subgroups as follows: early PPD (risk of depression at T1), late PPD (risk of depression at T2), and chronic PPD (risk of depression at T1 and T2).
Results: The results demonstrated that women who suffered trauma in childhood had significantly higher EPDS scores at both time points evaluated when compared to women who did not suffer from trauma. However, there was no significant difference in EPDS scores over time or in the interaction between time and childhood trauma, indicating that PPD scores and the impact of childhood trauma on PPD remained constant over time. All types of childhood trauma were significantly associated with late or chronic PPD. Emotional abuse, physical abuse, and emotional neglect are significantly associated with early PPD.
Conclusions: The present study demonstrated that women who experienced childhood trauma had significantly greater symptoms of PPD. However, PPD symptoms did not vary between the two assessments and remained stable. Mental health screening and interventions must be adopted during pregnancy monitoring and in the postpartum period.

Introduction: Previous research suggests that sexual dysfunction (SD) can both contribute to and result from depression. Additionally, evidence indicates that antidepressants may cause SD as a side-effect. However, knowledge of SD patterns in depressed individuals at the population level remains limited.
Objectives: To describe and compare the prevalence and incidence of SD during a three-year period before and after a diagnosis of depression.
Methods: Nationwide health registers in Sweden were used to identify patients diagnosed with a new-onset depressive episode (ICD-10: F32 and F33) in specialized healthcare between 2006 and 2014. SD was defined as having an SD diagnosis (ICD-10: F52.0-52.3) or a filled prescription of a drug aimed against SD (phosphodiesterase 5 inhibitor) for women and men separately. First, the prevalence of SD was calculated for the three-year period before and after the depression diagnosis. Second, annual incidence rates of SD were calculated by only including the first-ever SD event for each year during the same periods. Finally, in men, the annual incidence rates of SD were stratified by age groups (18–29, 30–49, and 50–65 years).
Results: We identified 110,725 women (mean age 38 years) and 73,566 men (mean age 39 years) with newly diagnosed depression. Among the women, 117 had SD in the three years before the depression diagnosis, corresponding to a three-year prevalence of 0.12% (95% CI 0.10%–0.14%), whereas 192 had SD in the 3 years after the depression diagnosis, corresponding to a 3-year prevalence of 0.19%, 95% CI 0.17%–0.22%). The annual incidence of SD

ranged from 0.03%–0.09% with the highest incidence in the first year after depression. Among the men, 4,299 had SD in the 3 years before the depression diagnosis, corresponding to a 3-year prevalence of 6.4% (95% CI 6.2%–6.6%), whereas 5,716 had SD in the 3 years after the depression diagnosis, corresponding to a 3-year prevalence of 8.6% (95% CI 8.4%–8.8%). The annual incidence of SD ranged from 1.4%-2.2%, with the highest incidence in the first year after depression. When stratified by age, the annual incidence of SD in men was lowest in the youngest group (18-29 years: 0.2%–0.8%) compared to the older age groups (30-49 years: 1.4%–2.6%; 50-65 years: 2.2%–3.3%).
Conclusions: In this study of patients with specialist treated depression, SD was significantly more commonly diagnosed and/or treated in the three-year period after the depression diagnosis than before in both women and men. Furthermore, the incidence of SD was highest in the first year after the depression diagnosis. As expected, SD was more common among men, where it also increased with age.

doi: 10.1192/j.eurpsy.2025.474

Introduction: Older adults with treatment-resistant depression (TRD) can be treated with augmentation or switched to a different drug.
Objectives: We aimed to identify factors that moderate the effectiveness of these strategies on treatment outcomes to guide the selection of the optimal strategy for each patient.
Methods: We analyzed data from 742 older adults with TRD in the Outcomes of Treatment-Resistant Depression in Older Adults (OPTIMUM) clinical trial. All participants were randomized to one of two treatment strategies, which were augmentation with aripiprazole, bupropion, or lithium; or switching to bupropion or nortriptyline. Treatment outcomes were change in MADRS scores and remission after 10 weeks. Age, burden of comorbid physical illness, number of adequate previous antidepressant trials, presence of executive cognitive impairment, and clinically relevant comorbid anxiety were examined as potential moderators of the effect of the two treatment strategies (augmentation vs. switching) on treatment outcomes.
Results: Overall, augmentation produced more improvement in MADRS scores and produced a higher rate of remission than switching. For change in MADRS scores after 10 weeks of treatment, the number of adequate previous antidepressant trials was the only significant moderator of the superiority of augmentation over switching (b = -1.6, t = -2.1, p = 0.033, 95%CI [-3.0,-0.1]). There were no significant moderators for remission.
Conclusions: Older patients with TRD with less than three previous antidepressant trials benefit more from augmentation than from switching. Future studies validating this finding with different drugs in more diverse samples can facilitate their application in real world settings.

Characteristics of patients with perinatal depression in UK primary care settings

C. Gillis[1], S. Chen[1], C. Mak[1], E. Tworkoski[1], L. Li[1], S. Eaton[1], C. Green[2], N. Maserejian[1] and M. Koch[1]*

[1]Biogen, Cambridge, United States and [2]Biogen, Maidenhead, United Kingdom

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.475

Introduction: Perinatal depression (PND) is a debilitating mood disorder that occurs during or following pregnancy. Information regarding characteristics associated with PND can aid in better understanding the disease.

Objectives: Examine patient characteristics and comorbidities of PND patients and matched non-PND controls in a UK electronic health record (EHR) database.

Methods: Women aged 12-55y with a delivery record (livebirth, stillbirth, mixed birth) during Jan 2017-Dec 2021 were selected from the Clinical Practice Research Datalink (CPRD) GOLD primary care database via a pregnancy algorithm. PND was ascertained using read codes during pregnancy or one year after the end of pregnancy date (EPD). Two ways to define PND were explored: 1) restricted definition (PND-r) where only PND codes were included; 2) broad definition (PND-b) including both PND and 34 other depression codes. For each PND case, two controls were matched on key patient variables such as age, depression history, and pregnancy outcome. Patients were required to have at least 12 months (mo) of continuous enrollment prior to and post EPD. Patient characteristics and select psychiatric and pregnancy-related comorbidities were compared, and prevalence rate ratios (PRR) and 95% Wald confidence intervals (CI) were calculated comparing cases and controls.

Results: The study included 2,214 cases of PND-r and 4,718 cases of PND-b, and their respective non-PND matched controls. PND-r and PND-b cases differed in timing of diagnosis. Of the PND-r cases, 6% were diagnosed during pregnancy and 47% in the first 3mo following delivery; whereas the distribution in the PND-b was, respectively, 18% and 30%. The mean age of the PND-r and PND-b cohorts was consistent (29y, SD=6). A prior recorded history of depression was present in 36% of PND-r cases and 43% of PND-b cases. Approximately 55% of PND-r cases and 65% of PND-b cases had a history of antidepressant use prior to last menstrual period.

During the 12mo pre-EPD, PND-r cases had higher prevalence of hyperemesis gravidarum (PRR=1.5, 95% CI 1.3-1.8), gestational diabetes (PRR=1.4, 95% CI 1.1-1.7), and anxiety/panic disorders (PRR=1.8, 95% CI 1.3-2.3) compared to controls. During the 12mo post-EPD, PND-r cases had higher prevalence of comorbid anxiety/panic disorders (PRR=3.8, 95% CI 3.0-4.9) as well as post-traumatic stress disorder (PRR=3.1, 95% CI 1.5-6.1) compared to controls. Results were similar in the PPD-b analyses, but with higher PRR of anxiety/panic disorders (post-EPD PRR: 11.2, 95% CI 9.7-12.9).

Conclusions: 80% of PND-r and 71% of PND-b cases were diagnosed during pregnancy or in the first 6mo following EPD. Cases had higher prevalence of certain pregnancy and psychiatric conditions compared to controls, with comorbid anxiety/panic disorder estimates higher using the PND-b definition. Future research should consider comparing results using both broad and restricted definitions of PND in EHRs.

Diagnostic Potential of Cross-Questionnaire Analysis for Depression and Memory Disorders Using Machine Learning Techniques

M. Balkoudi[1], N. Arnaoutoglou[2,3]*, K. Fountoulakis[2], A. Saitis[2], G. Deretzi[4], I. Diakogiannis[3] and D. Hristu-Varsakelis[1]

[1]Department of Applied Informatics, University of Macedonia; [2]3rd Dpt Of Psychiatry; [3]1st Dpt Of Psychiatry, Aristotle University Thessaloniki and [4]Neurology Clinic, Papageorgiou General Hospital, Thessaloniki, Greece

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.476

Introduction: Research shows a strong correlation between depression and memory disorders, suggesting the potential for cross-questionnaire data use in automated diagnostic systems. This study explores whether the Prospective and Retrospective Memory Questionnaire (PRMQ) can identify depressive symptoms and if the ZUNG Self-Rating Depression Scale (SDS) can predict memory-related disorders.

Objectives: To evaluate the effectiveness of using questionnaires intended for one mental disorder to diagnose another through

machine learning models on data from a large-scale self-assessment online questionaire.
Methods: The study is part of the Memory and Depression Study: MANDY, conducted by the 1st Department of Psychiatry and the Department of Neurology of Papageorgiou Hospital, Thessaloniki, Greece. Data from 3340 participants were collected via an online survey containing the PRMQ, SDS, demographic data, and health-related questions. Four predictive tasks were designed: two for predicting depression using memory responses (D-from-M score and class) and two for predicting memory disorders using depression responses (M-from-D score and class). Machine learning models including LightGBM, AdaBoost, Support Vector Machines, and Logistic Regression were evaluated. Performance metrics included precision, recall, F1-score, and AUC-ROC (Figure 1).
Results: The LightGBM classifier was the top-performing model for the D-from-M class prediction task, achieving a precision of 0.75563, recall of 0.79125, an F1-score of 0.77303, and an AUC-ROC of 0.79319 on the test set (Table 1). This indicates a strong predictive capability for diagnosing depression from memory-related responses. The AdaBoost classifier had similar performance but was slightly inferior to LightGBM. For the M-from-D class task, the class imbalance (memory disorder prevalence at 5%) was a significant challenge. The best model, a Support Vector Classifier with ADASYN resampling, achieved a precision of 0.6, recall of 0.375, an F1-score of 0.46154, and an AUC-ROC of 0.86218. However, its performance was notably lower than LightGBM in predicting depression.

Image 1:

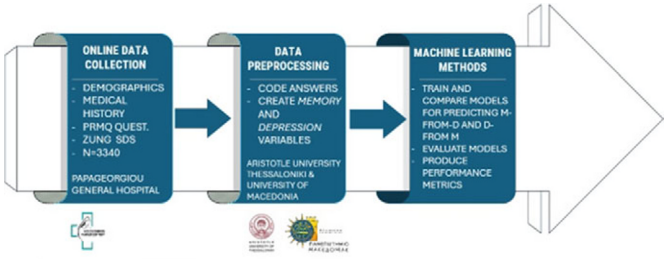

Figure 1. Flowchart of MANDY Study

Image 2:

Model	Precision	Recall	F1-Score	AUC-ROC
LightGBM	0.75563	0.79125	0.77303	0.79319
AdaBoost	0.75244	0.77778	0.7649	0.78646

Table 1: Classification Performance Metrics for D-from-M Class Prediction

Conclusions: The PRMQ, combined with specific demographic and health-related questions, showed promise in predicting depression, with the LightGBM classifier as the best overall model. This underscores the potential for cross-questionnaire data utilization for diagnosing depression. Conversely, predicting memory disorders using the SDS was less effective, indicating the need for more targeted diagnostic tools. Future research should include neurocognitive and biomarker data to enhance diagnostic accuracy for memory-related conditions.

Digital Phenotyping in Mental Health - What can it mean for the future of Psychiatry?

M. J. Brito[1,2*] and J. D. Vieira-Andrade[1,2]

[1]Serviço de Psiquiatria, Unidade Local de Saúde de Coimbra and [2]Instituto de Psicologia Médica, Universidade de Coimbra, Coimbra, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.477

Introduction: Smartphones, central to modern life, offer a cost-effective tool for gaining patient insights outside the consultation room. Through passive data collection (e.g., sensor data) and active questioning, smartphones enable ecological assessments of psychiatric symptoms and self-reported experiences. This "moment-by-moment quantification of the individual-level human phenotype in situ using data from personal digital devices" via digital phenotyping (DP) has garnered significant research attention, showing potential for early detection and intervention in mental health.
Objectives: We explore recent DP developments in mental health, highlighting its potential to transform clinical practice while acknowledging challenges and risks.
Methods: Narrative literature review resorting to PubMed and Google Scholar using keywords such as "digital phenotyping", "digital phenotype", "digital biomarker" and "mobile sensing".
Results: DP studies, particularly in Mood Disorders and Schizophrenia, mostly rely machine learning for data analysis. Biomarkers from passive data (e.g., GPS, social connectivity, physical activity) correlate with self-reports and clinical measures of depression, anxiety, mania, and psychosis. Speech and text analysis through Natural Language Processing (NLP) offers new research avenues. DP promises early detection, relapse prevention, and treatment monitoring but faces challenges, including privacy concerns, and low user engagement - that could be solved by closing the loop by returning individual research results or a tailor-made intervention. Nevertheless, regulation and good practice standards are still lacking, posing the threat of diagnostic inaccuracy and undeniable iatrogenic risk.
Conclusions: For DP to fully realize its potential, integration with standard care and existing systems is essential. While risks exist, when comparing DP with other medical interventions currently

under research, perils are minor. Mental health care urgently needs disruptive innovation to improve access and quality.

The Anxiety of the 21st Century: The Paradox of Nomophobia. A Critical Examination of the Phenomenon in a Population with Eating Disorders

F. Marcolini[1]*, G. Buffa[1], B. Ferrari[1], D. De Ronchi[1] and A. R. Atti[1]

[1]Department of Biomedical and Neuromotor Sciences , University of Bologna, Bologna, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.478

Introduction: In the present era, technology and medicine have become deeply intertwined, forming inseparable scientific disciplines. The mobile phone has become an omnipresent device, serving functions such as financial management, job organization, social networking, and internet access. While its benefits are undeniable, there is growing evidence of its potential pathological effects. One of the most recently identified issues is nomophobia—a term combining "no mobile," "phone," and "phobia," which refers to the fear or anxiety of being without one's mobile phone.
Nomophobia is considered a situational phobia of the contemporary era. Its symptoms include excessive reliance on mobile phones and pervasive anxiety about losing internet connectivity. Related conditions include "Ringxiety" and "phantom vibration syndrome," where individuals perceive false notifications from their devices.
Objectives: This study aims to assess the relationship between eating disorders (ED) and nomophobia. Additionally, it seeks to analyze the psychopathological components of nomophobia and evaluate the characteristics of the Nomophobia Questionnaire (NMP-Q), currently used for its assessment.
Methods: A questionnaire was administered at the Study and Care Unit for ED in Bologna, Italy, between January 2023 and May 2024. Alongside tests evaluating the social and psychopathological characteristics of the outpatients (including the STAI-Y for anxiety assessment), the Italian version of the NMP-Q was employed.
Results: The study included 104 patients (97 females and 7 males) with an average age of 21.8 years (range 18-44). The results showed that 100% of the subjects exhibited symptoms of nomophobia, with 21.3% displaying severe nomophobia. Among these, 94.4% tested positive for state anxiety, and 100% for clinically significant trait anxiety. This suggests that nomophobia may reflect not only current anxiety symptoms but also an anxious trait, indicating a predisposition to heightened reactivity and anxiety in response to environmental stimuli.
Conclusions: The data highlight the alarming pervasiveness of internet addiction in contemporary society, with nomophobia being a significant manifestation. Given its substantial consequences, it is crucial to deepen our understanding of this condition and its underlying psychosocial determinants. This will enhance our knowledge and aid in developing more effective prevention strategies. However, a paradox arises: if nearly everyone is affected by nomophobia, it challenges the traditional definition of a disease. Further research into the NMP-Q test's structure and specificity is necessary, as high prevalence rates may question its current measurement validity.

Assessing demographic and clinical determinants of resilience, personal recovery, and quality of life for psychiatric in-patients before hospital discharge

E. Owusu[1]*, W. Mao[1], R. Shalaby[1], H. Elgendy[1], B. Agyapong[1], E. Eboreime[2], M. A. Lawal[1], N. Nkire[1], C. T. Hilario[3], P. Silverstone[1], P. Chue[1], X.-M. Lin[1], Y. Wei[1], W. Vuong[4], A. Ohinmaa[5], V. Taylor[6], A. J. Greenshaw[1] and V. I. Agyapong[1,2]

[1]Psychiatry, University of Alberta, Edmonton; [2]Psychiatry, Dalhousie University, Halifax; [3]Nursing, University of British Columbia, Okanagan; [4]Addiction and Mental Health, Alberta Health Services; [5]School of Public Health, University of Alberta, Edmonton and [6]Psychiatry, University of Calgary, Calgary, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.479

Introduction: Many patients with mental health and emotional problems often see the transition period in the community after hospital discharge as a test of their resilience and a threat to their recovery. Most often, some doubt their ability to cope with the everyday challenges that may confront them in the community.
Objectives: This paper assesses how demographic and clinical characteristics predicted resilience, personal recovery and quality of life.
Methods: Data were collected from psychiatric inpatients prior to their discharge into the community using the REDCap, an online survey platform. Resilience, personal recovery, and quality of life were assessed using the Brief Resilience Scale (BRS), Recovery Assessment Scale (RAS), and EQ-Visual Analogue Scale (EQ-VAS), respectively. One-way analysis of covariance between groups (ANCOVA) was conducted to compare the relationships between groups. The dependent variables comprised mean scores of BRS, RAS and EQ-VAS. Demographic and clinical variables such as age, gender, ethnicity, and mental health diagnosis groups were independent variables, and covariates comprised demographic/clinical factors such as gender, ethnicity, and mental health diagnosis
Results: The survey results indicate that males had significantly higher resilience scores compared to females (Mdiff = 0.270, CI= 0.144– 0.397, p=.<.001) and others (Mdiff =0.470, 0.093- 0.846, p=<.001); Black people indicated significantly higher quality of life than Caucasians (Mdiff = 8.79, 2.73- 14.85, P= <.001), and Indigenous people (Mdiff = 14.50, 6.45 - 22.51, p=<.001), respectively. In terms of relative recovery, participants with depression had significantly lower recovery compared to those with bipolar disorder (Mdiff = -10.25, -14.40- -6.10, p=<.001), schizophrenia (Mdiff f = -8.60, -13.20- -3.99, p=<.001), and substance use disorder (Mdiff = -8.30, -15.50- -1.42, p=<.005).

Conclusions: The present results indicate that women, younger adults, and Indigenous peoples may be more challenged in adapting to the challenges of post-discharge life in the community. Our data may be helpful in communicating to policymakers and providers of funds the need to implement and evaluate outcomes of inpatient and community programs focusing on supporting resilience to improve recovery outcomes after discharge from the patient setting.

Redefining virtual mental health services: youths' perspectives and ideal features

E. Samari[1]*, J. A. Vaingankar[1], S. Chang[1], A. S[1], Y. C. Chua[2], C. Tang[3], Y. P. Lee[3], M. Subramaniam[1,4] and S. Verma[5,6]

[1]Research Division; [2]Department of Psychosis; [3]CHAT, Centre of Excellence for Youth Mental Health, Institute of Mental Health; [4]Saw Swee Hock School of Public Health, National University of Singapore; [5]Institute of Mental Health and [6]Duke-NUS Medical School, Singapore, Singapore
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.480

Introduction: The COVID-19 pandemic prompted a significant shift in our approach to healthcare, leading to the widespread adoption of virtual healthcare services, including mental healthcare. In this context, understanding and incorporating the unique perspectives of youths is crucial for improving virtual mental health services for this population.
Objectives: This qualitative study explores the ideal features of virtual mental health services among youths.
Methods: Nine focus group discussions and eight semi-structured interviews were conducted with 65 individuals aged 15-35 in Singapore. To ensure the comprehensive representation of youths' perspectives, participants from diverse ethnicities (mainly Chinese, Malay, and Indian), ages, and genders were included using purposive sampling. The data was analysed using content analysis through both inductive and deductive approaches.
Results: Four main themes were identified from the data. First, technology and platform: youths stressed the importance of a credible and government-endorsed service provider to deliver a comprehensive and trustworthy experience facilitated by qualified professionals. Second, functionality: they wanted credible affiliations to be displayed prominently on the home page and various tools such as calls, chats, moderated forums, profiles of healthcare professionals, and educational resources. Confidentiality, anonymity, and privacy were also highlighted as necessary. Third, user interface: youths preferred an intuitive and age-tailored interface to ensure a seamless and user-friendly experience, with organised content, appealing aesthetics, and engaging elements on video call sessions. Fourth, usability: they emphasised the need for an affordable and widely compatible operating system to promote accessibility of services.
Conclusions: Virtual mental health services, with their great potential, can expand and effectively meet the needs of youths. By prioritizing credible platforms, comprehensive functionality, confidentiality, an intuitive interface, and broad accessibility, we can enhance help-seeking among youths and create a more effective support system.

The Level of Community Integration in Adults with Psychiatric Disorders

E. D. Cindik-Herbrueggen

Psychiatry, Neuro-Psychiatric Center, München, Germany
doi: 10.1192/j.eurpsy.2025.481

Introduction: In the post-migration period, individuals from diverse religious, linguistic, cultural, and traditional backgrounds strive to coexist in a shared social space. However, numerous adaptation challenges arise during this process. Additionally, individual personality traits significantly influence experiences during this time. For those suffering from psychiatric disorders, the integration process becomes even more complex, as these conditions can diminish an individual's ability to cope with stress, making societal integration more difficult. This study aims to examine the level of integration among individuals with psychiatric disorders who have faced challenges after migration, with the goal of contributing to initiatives that facilitate their adaptation process.
Objectives: This study aims to assess the integration levels of individuals with psychiatric disorders into society. In addition to examining psychiatric conditions, sociodemographic data will also be collected from participants to explore how additional factors influence the integration process. By doing so, the study seeks to provide insights that can inform efforts to facilitate the integration of these individuals into society.
Methods: Data were collected from 91 participants, primarily first- and second-generation Turkish immigrants with at least one psychiatric disorder, at the Neuro Psychiatric Center Riem (NPZR) clinic. The study employed the "Community Integration Scale for Adults with Psychiatric Disorders" along with a sociodemographic questionnaire, with informed consent obtained from all participants. SPSS analysis software was utilized to examine the relationship between integration levels and other relevant variables.
Results: Statistical analyses indicate that variables such as age, education level, smoking, and drug use significantly affect the total score.
Conclusions: These findings reveal that individuals' demographic and behavioral characteristics play a significant role in overall performance and achievement measures.

Unraveling Burnout, Diabetes Distress, and Depression: Insights into Their Impact on Adults with Diabetes

S. Er[1]*, M. Murat Mehmed Ali[2], G. Anataca[3] and S. Çelik[4]

[1]Department of Mental Health and Psychiatric Nursing, Istanbul University – Cerrahpaşa, Florence Nightingale Faculty of Nursing; [2]Psychiatric Nursing Department, University of Health Sciences, Hamidiye Faculty of Nursing; [3]Kanuni Sultan Suleyman Education and Research Hospital, Istanbul Health Sciences University and [4]Department of Internal Medicine Nursing, University of Health Sciences, Hamidiye Faculty of Nursing, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.482

Introduction: Diabetes burnout refers to the physical and emotional fatigue resulting from the challenges of living with and managing diabetes. It is a prevalent issue that significantly affects diabetes care. Unfortunately, it often receives less attention and is frequently underestimated.
Objectives: This study examined the prevalence and predictors of burnout, diabetes distress and depression in adults with diabetes mellitus.
Methods: In this cross-sectional study, investigated the Turkish validity and reliability of the Diabetes Burnout Scale and determined prevalence and predictors burnout, diabetes stress, and depression among adults with DM. The study sample consisted of 315 adults and a Personal Information Form, the Diabetes Burnout Scale, the Diabetes Distress Scale, and the Patient Health Questionnaire-8 were administered. Data analysis involved descriptive tests, Pearson correlation analysis, and the use of SPSS (v.29).
Results: As a result of confirmatory factor analysis, it was determined that the Turkish version of the Diabetes Burnout Scale had 3 sub-dimensions and consisted of 12 items. The Cronbach alpha reliability coefficient of the total scale was found to be 0.814. Participants had a mean (±SD) age of 48.63 (±8.23) years, with a majority (54.6%) being male and (±93.7%) diagnosed with type 2 diabetes mellitus. The median duration of diabetes among them was 4.41 (±2.48) years, and their median HbA1c level was 8.99 (±0.68). The prevalence rates for burnout, diabetes distress, and depression were found as 2.69 (±0.28), 4.64 (±0.40), and 15.20 (±3.88), respectively. Additionally, the total burnout score showed a positive correlation with both the diabetes distress score ($r = 0.556$, $p = 0.033$) and depression ($r = 0.325$, $p = 0.027$).
Conclusions: The study revealed a high prevalence of burnout, distress, and depression, highlighting the need for a prevention strategy. Monitoring high-risk groups for pre-diabetes and diabetes is crucial for informing health programs and resource distribution to manage the condition effectively.

Prediction of dementia following traumatic injury with risk score (the DEMTIS): a multivariable prediction model development study based on Hong Kong electronic health records

C. S. FUNG[1]*, H. F. CHUNG[2], S. H. CHEUNG[2], N. DONG[2], I. T. K. HUI[2], C. S. M. WONG[3], W. C. CHANG[1] and P. W. CHENG[1]

[1]Department of Psychiatry; [2]Department of Psychology and [3]School of Public Health, The University of Hong Kong, Hong Kong, Hong Kong
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.483

Introduction: Patients following traumatic injury (TI) are at increased risk of developing dementias, yet an efficient, validated screening instrument is lacking.
Objectives: In the current study, we developed the Dementias following Traumatic Injury Screening (DEMTIS) score, a brief post-TI dementias screening tool.
Methods: We identified 270,843 electronic health records from Hong Kong patients admitted for TI between 2001 and 2021. The records were randomly split into training (80%; n=258,739) and testing cohort (20%; n=50,883). The DEMTIS was developed based on a backward stepwise multivariate Cox proportional hazard model predicting first-ever dementia diagnosis. Competing risk survival analyses were used to predict the risk of Alzheimer's disease (AD) and vascular dementia (VD), while taking the risk of other dementias into account. Model discrimination of the three scores was evaluated using concordance statistics (c-statistic) calculated as the area under the receiver operating characteristic curve. Statistical significance was set at $p<.01$.
Results: The 5-year, 10-year, and 20-year risk of all-cause dementias following TI was 2.1% (95% CI 0.020-0.021), 3.8% (95% CI 0.037-0.039), and 6.5% (95% CI 0.063-0.066), respectively. The final model included sex, TI characteristics, physical covariates, history of mood and anxiety disorders, and cerebral degenerative disease (See Table 1). The population mean of DEMTIS was 59.45 (SD=21.29). The optimal threshold of DEMTIS predicting dementia was determined at 75 using the closest top left rule. Individuals at high risk (DEMTIS≥75) were associated with a 6.0% (95% CI 0.059-0.061) risk of dementia in 5 years, whereas those at low risk were associated with a 0.5% (95%CI 0.004-0.005) risk (see Figure 1; Figure 2). The model predicting 5-year dementia has an overall c-statistic of 0.835 (95% CI 0.832-0.839) in the testing data (see Figure 3). We further developed risk scores for 5-year AD and VD based on the findings from competing risk models; the c-statistics of model for AD and VD are 0.857 (95% CI 0.844-0.871) and 0.837 (95% CI 0.821-0.853) respectively.

Table 1: Calculation of the DEMTIS

Variables	DEMTIS	DEMTIS-AD	DEMTIS-VD
Sex			
Male	0	0	0
Female	2	1	1
Age of TI	1	1	1
Position of TI			
Head injury	1	-1	2
Torso	1	2	1
Upper Limb	2	2	2
Lower Limb	0	0	0
Fracture types		NA	
Opened	-1		-1
Closed	0		0
Unspecified	-1		-1
Hypertension			
Yes	2	-1	3
No	0	0	0
Hyperlipidemia			
Yes	2	-1	2
No	0	0	0
CCI	-1	-1	2
Cerebral degenerative disease			
Yes	3	3	3
No	0	0	0
Mood and anxiety disorder			
Yes	2	2	NA
No	0	0	

Image 1:

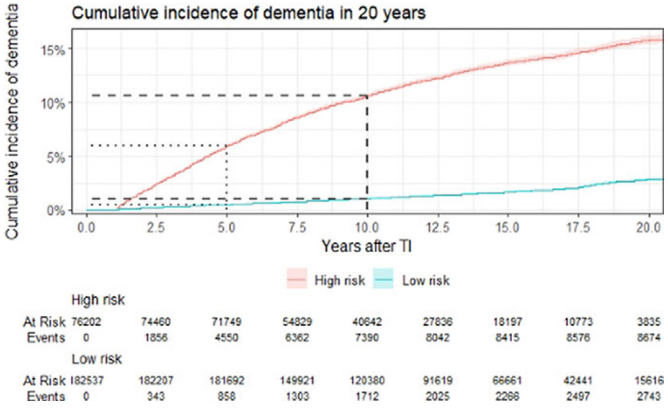

Image 2:

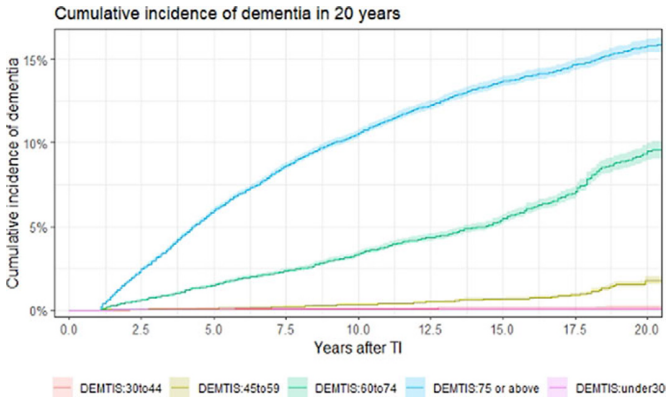

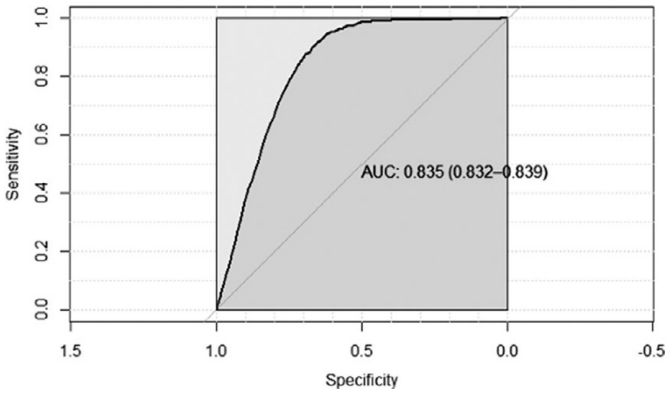

Image 3:

Conclusions: As a novel, easily accessible screening instrument, DEMTIS can identify patients at elevated risk of dementia following TI. It assists clinicians in evaluating patients' risk of dementia and providing personalized care.

Coping Strategies and Family Crisis Among Relatives of Intensive Care Unit Patients

Z. Konstanti[1]*, M. Kourakos[1], F. Tatsis[1], S. Georgakis[1], G. Papathanakos[2], M. Gouva[1] and V. Koulouras[2]

[1]Department of Nursing, School of Health Sciences, University of Ioannina, Research Laboratory Psychology of Patients, Families & Health Professionals and [2]Department of Intensive Care Medicine, University Hospital of Ioannina, Ioannina, Greece
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.484

Introduction: The admission of a patient to the Intensive Care Unit (ICU) often triggers intense stress symptoms in their family members, leading to anxiety, depression, and emotional distress.
Objectives: To investigate the coping mechanisms employed by family members of critically ill patients, considering their sociodemographic characteristics and the closeness of their relationship to the patient.
Methods: The study included first-degree relatives, close relatives, and intimate friends of ICU patients. Data were collected through written questionnaires completed by family members who visited patients during the first week of treatment. A sociodemographic questionnaire and the Family Crisis Oriented Personal Evaluation (F-COPES) scale were used to assess coping strategies.
Results: A total of 223 family members, with a mean age of 41.5 ± 11.9 years, participated in the study. This sample represented 147 critically ill patients. Of the participants, 81 (36.3%) were men and 142 (63.7%) were women. The majority were the patients' children (40.8%), siblings (19.3%), or companions (16.1%). The most frequently employed coping strategies were seeking social support (mean score 31.27 ± 4.72), mobilizing the family for help (mean score 14.26 ± 3.17), and adopting a passive approach (mean score 14.04 ± 2.81). Offspring and male relatives were less effective in using coping strategies compared to other relatives and female participants, respectively.
Conclusions: Family members of critically ill patients are psychologically vulnerable, experiencing significant emotional distress. They often rely on external support to cope with the family crisis. Health professionals should prioritize understanding and addressing the specific needs of these relatives to provide appropriate support.

EPP153

Evaluation of Depression, Anxiety, Stress, and Burnout Levels Among Emergency and Intensive Care Unit Professionals

S. Kukurt[1]*, G. Dokuz[1], O. Kilic[1], Z. L. Onat[1], M. Combas[1] and I. Kirpinar[1]

[1]Psychiatry, Bezmialem Vakif University, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.485

Introduction: Emergency departments (ED) and intensive care units (ICU) are high-stress environments where healthcare professionals are continuously exposed to critical situations. This results in substantial mental health burdens, leading to increased levels of depression, anxiety, stress, and burnout. These issues negatively affect both the well-being of professionals and patient care.
Objectives: This study aims to evaluate the prevalence and severity of depression, anxiety, stress, and burnout among ED and ICU professionals. The goal is to understand mental health issues and identify contributing factors to improve prevention and support systems.
Methods: A total of 242 healthcare professionals from Bezmialem Vakif University Hospital were included: 120 ICU staff (80 females, 40 males), 66 ED personnel (42 females, 24 males), and 56 office personnel (38 females, 18 males) serving as a control group. The study employed validated instruments: the Beck Depression Inventory, the Beck Anxiety Inventory, Perceived Stress Scale, and Maslach Burnout Inventory. Non-parametric tests (Kruskal-Wallis H and Chi-Square) were used due to non-normal data distribution, with pairwise comparisons adjusted using Bonferroni correction. The significance level was set at $p < 0.05$.
Results: The results showed significant differences in age, depression scores, stress levels, and burnout indicators between the ICU, ED, and control groups. ICU and ED staff reported significantly higher depression scores compared to the control group ($p < 0.001$). Stress levels were also significantly elevated in ICU workers compared to office personnel ($p = 0.001$). Burnout indicators were notably higher in ICU professionals ($p = 0.011$). Conversely, no significant differences were observed in anxiety scores, emotional exhaustion, and hours of sleep.

Table 1: Summary of Key Results

Variable	ICU Personnel (n = 120)	ED Personnel (n = 66)	Office Personnel (Control, n = 56)	p-value	Significant Difference
Beck Depression Score (Median)	10	10	6	<0.001	Yes
Beck Anxiety Score (Median)	8	7	6	0.064	No
Perceived Stress Score (Median)	25.5	23	23	0.001	Yes (ICU vs. Office)
Maslach Depersonalisation Score (Median)	23.5	21	21	0.011	Yes (ICU vs. Office)
Maslach Personal Accomplishment Score (Median)	23.5	22	21	0.034	Yes (ICU vs. ED)
Maslach Emotional Exhaustion Score (Median)	22	21	21	0.064	No
Working Hours (Median)	60	55	40	<0.001	Yes
Living with Family/ Partner/Alone (%)	65% / 25% / 10%	60% / 30% / 10%	70% / 20% / 10%	0.232	No
Satisfaction with Job (%)	65%	70%	80%	0.147	No

Conclusions: The findings underscore the necessity for targeted interventions to reduce psychological distress among ED and ICU professionals. Implementing support systems, promoting work-life balance, and improving mental health resources can significantly alleviate the mental burden on these professionals, thereby enhancing both their well-being and patient care quality.

The impact of the new Dutch law on Court-Orders or Care Authorizations: Less or Shorter involuntary Admissions due to Earlier Intervention?

M. Lungu[1]*, S. Gemsa[1] and E. Noorthoorn[1]

[1]GGNet, Warnsveld, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.486

Introduction: As of January 1, 2020, the new Dutch Mental Health Compulsory Care Act (WVGGZ) came into effect, replacing the Special Admissions to Psychiatric Hospitals Act (Wet BOPZ).
Objectives: One of the expectations of the WVGGZ was that earlier (medication-based) involuntary intervention in outpatient settings would lead to fewer or shorter hospital admissions. The most important change was the outpatient use of involuntary medication, which was not allowed before the law.
Methods: Data from the Argus rating scale (Noorthoorn et al, 2016) and its successor, the compulsory care registration were combined with background data on admissions and wards. For this study, patients with a court order (RM) in 2016 and 2017 and a cumpulsory care authorization (ZM) in 2022 and 2023 were selected.
Results: In 2016 and 2017, 549 patients received an RM, and 958 RM's were issued. In 2022 and 2023, there were 405 patients, and 546 ZM's were implemented. The total number of admission days for these patients before the law was 78,183 compared to 76,099 after the law. The average length of stay increased from 81 days per patient to 140 days per patient (t=-8.93, p<0.001). Seclusion decreased from 45,893 hours to 2,985 hours (t=4.93, p<0.001). Intramuscular (IM) medication was administered 137 times before the law and 369 times in clinical settings after the law (2022-2023) (chi-square= 325.10, p<0.001). IM medication was administered 777 times in outpatient settings.
Conclusions: Contrary to expectations, the legislative change did not result in shorter admissions for patients with a ZM. The data indicate significant differences in involuntary treatment for patients before and after the legal change. The presentation will explore possible factors influencing these figures.

Predictors of Treatment Completion Among Clients Involved with the U.S. Public Mental Health System

S. Yampolskaya[1]*, L. Callejas[1] and C. Walker-Egea[1]

[1]Child & Family Studies, University of South Florida , Tampa, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.487

Introduction: Research indicates that for psychiatric services to be generally effective, individuals have to complete the treatment. Although treatment completion does not necessarily equate to treatment success, it has been found to consistently lead to improved outcomes including improved rates of recovery and reduced risk of involvement with the justice system and other adverse outcomes. Treatment non-completion, on the other hand, has been associated with a higher risk of readmissions for inpatient care, legal, and other health-related problems (*Dreyer et al.* S Afr J Psychiatr 2020; 26 a1255). These findings underscore the importance of examining factors associated with treatment completion.
Objectives: The goal of the study was to identify predictors for treatment completion among individuals receiving psychiatric services from state-administered behavioral health systems in Indiana, USA. Three domains of predictors were examined, including sociodemographic characteristics, comorbid conditions, and the type of treatment patients received.
Methods: Statewide records from merged administrative data sets were used for this analysis. Multivariate logistic regression was conducted using a sample of 15,412 adults receiving behavioral health services in fiscal year 2020.
Results: Among demographic characteristics only race was associated with treatment completion. Individuals who were non-Hispanic White were 20% more likely to complete their treatment compared to their minority (e.g., Black, Hispanic) counterparts ($p < .05$, OR = 1.20). Having more than one mental health disorder was associated with 16% decreased odds of completing treatment ($p < .05$, OR = 0.87). Individuals who were institutionalized for psychiatric conditions had 26% decreased odds of completing the treatment ($p < .05$, OR = 0.80), but those who received inpatient substance abuse related care were over four times more likely to complete their treatment ($p < .05$, OR = 4.61). Finally, individuals who attended any self-help groups had 63% greater odds of completing the treatment.
Conclusions: Findings suggest that individuals who simultaneously received substance abuse and mental health treatment had the greatest chances to complete treatment successfully. Study implications also suggest that self-help or support groups should be promoted as ways to motivate patients to adhere to treatment.

Differences in Cognitive Performance Between Individuals at Familial High Risk for Schizophrenia or Bipolar Disorder and Healthy Controls: a Systematic Review and Meta-Analysis

B. Pedruzo[1]*, C. Aymerich[1], A. Yorca[2], R. Magdaleno[2], A. Diaz Pons[2], C. Martinez[2], V. Ortiz[2], M. A. Gonzalez-Torres[1], R. Ayesa-Arriola[2] and A. Catalán[1]

[1]Department of Psychiatry, Basurto University Hospital, Bilbao and [2]Department of Psychiatry, Valdecilla Biomedical Research Institute, Santander, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.489

Introduction: Schizophrenia and bipolar disorder are severe psychiatric disorders influenced by genetic and environmental factors, sharing clinical features, risk factors, and genetic predispositions. Cognitive impairment is a central aspect of both disorders, affecting various domains like memory, attention and executive function. Distinguishing disorder-specific cognitive impairments from those shared across psychoses is challenging. Research on Clinical High

Risk (CHR) and Familial High Risk (FHR) populations is vital for identifying cognitive impairments related to vulnerability. CHR populations exhibit cognitive changes, but the evidence on FHR populations remains less clear, even though offspring of individuals with severe mental disorders face a high risk of developing these conditions.
Objectives: This study aims to perform a meta-analysis of neurocognitive functioning in offspring of individuals with affective psychoes and non-affective psychoses, compared to healthy controls (HC-Off). This meta-analysis seeks to improve statistical power of individual studies and offer more reliable estimates of cognitive deficits related to genetic vulnerability to psychotic disorders.
Methods: Following PRISMA, MOOSE, and EQUATOR guidelines, a systematic literature search was conducted up to December 12th 2023. Articles were screened, and those relevant were assessed for eligibility. The inclusion criteria focused on original studies comparing neurocognitive performance between offspring of individuals with affective or non-affective psychoses and healthy controls. The primary outcome was the difference in performance across neurocognitive domains. Meta-analyses were conducted on the overall sample and separately for affective and non-affective offspring, using a random-effects model.
Results: Within the analyzed domains, individuals with affected parents performed significantly worse in every domain in comparison with control group, except in Motor Functioning domain. When studied separatley, offspring of parents with affective psychosis showed significant cognitive impairments in visual and verbal learning, processing speed, and memory, with smaller deficits in other domains. In contrast, offspring of parents with non-affective psychosis exhibited more severe impairments. Social cognition and motor functioning were less affected in both groups.
Conclusions: Key deficits in learning, memory, and general intelligence highlight the potential for these cognitive domains to serve as markers of vulnerability to psychosis. While both groups of offsrping show impairments, the more pronounced deficits in the non-affective group indicate a distinct cognitive risk profile. These insights may inform early interventions tailored to the specific cognitive challenges faced by high-risk populations.

Mindsets of Negative Emotions Mediate the Impact of Self-Compassion on Youth Mental Health: Evidence from a Three-Annual Wave Study

D. Qi[1]* and S. Zhu[1,2]

[1]Department of Applied Social Sciences and [2]Mental Health Research Centre, The Hong Kong Polytechnic University, Hong Kong, Hong Kong
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.490

Introduction: Accumulating evidence supports the mental health benefits of self-compassion. However, longitudinal research unravelling how self-compassion affects mental health outcomes is scarce.
Objectives: This study aimed to clarify whether mindsets of negative emotions serve as a mechanism of how self-compassion exerts impacts on youth mental health.
Methods: The longitudinal school-based survey was conducted annually across three years among 719 secondary school students (mean age: 14.65, SD: 0.72). Mediation models were examined with self-compassion at T1 as the independent variable, negative emotion mindsets at T2 as the mediator variable, and depression, anxiety, and life satisfaction at T3 as the dependent variables. Alternative mediation models with negative emotion mindsets at T1 as the independent variable and self-compassion at T2 as the mediator variable were also tested to corroborate the hypothesized direction of the mediation effects. The mediation models all controlled for age, sex, socioeconomic status (SES), and respective measurements of mediator and dependent variables at baseline.
Results: Negative emotion mindsets at T2 significantly and fully mediated the effects of self-compassion at T1 on mental health (indexed by depression, anxiety, and life satisfaction levels) at T3 (see Fig. 1, Fig. 2, and Fig. 3, respectively). The alternative mediation models were all insignificant, corroborating that negative emotion mindsets serve as the pathway through which self-compassion impacts mental health, rather than the reverse.

Image 1:

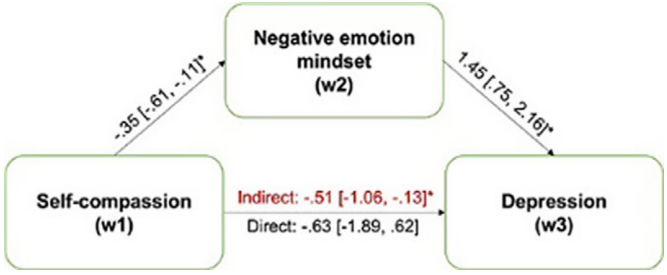

Image 2:

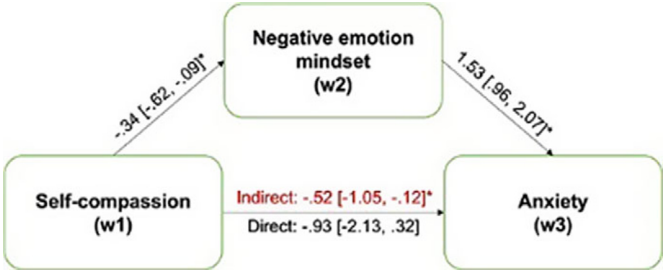

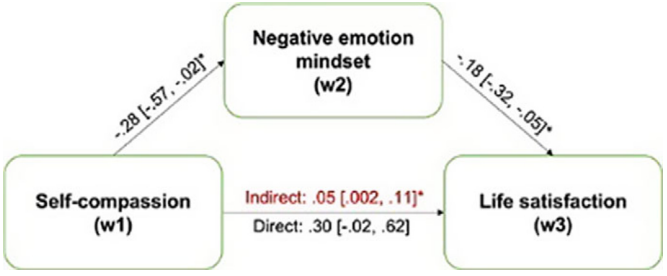

Image 3:

Conclusions: This study highlights the belief-in-change of negative emotions as a key mechanism underlying the impact of self-compassion, and has important implications for research and interventions aimed at promoting youth mental health.

EPP163

Deinstitutionalization in Georgia-why it is so slow

N. Zavradashvili[1]* and G. Matiashvili[1]

[1]School of Health Sciences, The University of Georgia, Tbilisi, Georgia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.491

Introduction: Mental health reform represents one of the most transformative changes in the field of healthcare, as it not only changes the forms of services, but also the nature of services offered. While many countries have successfully implemented such reforms, others, including Georgia, have struggled with a protracted and inconsistent process. Despite decades of advocacy by professionals for deinstitutionalization psychiatric hospital treatment continues to dominate in Georgia's mental healthcare system.
Objectives: The purpose of the review is to explore the concept of deinstitutionalization within the mental health landscape and assess its status in the context of Georgia. It aims to study the lessons learned from successful deinstitutionalization and illuminate achievements and challenges surrounding deinstitutionalization in Georgia's reality.
Methods: A qualitative analysis including desk review, in-depth interviews and focus group discussions was conducted. Proceeding from the research objectives we analyzed the existing legislation, strategic documents and clinical practices concerning individuals with mental disorders; Interviews were also conducted with key informants on the shortcomings and problems in deinstitutionalization practices
Results: The review findings reveal, that despite recent progress such as the development of community mobile teams and increased funding allocated for community services within mental health budget, a number of issues still remain a problem: there is no agreement among stakeholders on how to restructure existing hospital beds and financial provisions remains unresolved. The field of mental health in Georgia suffers from a lack of human resources. Attracting new personnel, ensuring regional distribution, and enhancing qualifications are necessary components of deinstitutionalization that require the involvement of all stakeholders, coordinated and time-planned action. The current mental healthcare system in Georgia is characterized by a lack of coordination and collaboration among its various components. Establishing patient care pathways between services with clear referral criteria is crucial for improving the efficiency of mental health services.
Conclusions: This research highlights that successful deinstitutionalization requires additional funds, time, and trained people. Institutions should have a long-term (3-5) year development plan, detailing the source of funding, activities to be implemented, and expected outcomes. In the absence of such a plan, progress remains sporadic, intermittent, uncoordinated, and less effective. By addressing identified challenges and promoting coordination among mental health components, Georgia can guide a more effective course toward a community-based, patient-centered mental healthcare system.

The effects of DBS treatment on OCD symptoms in pediatric and young adult patients with myoclonus-dystonia: a case series

X. Acosta-Villalobos[1]*, B. Pérez-Dueñas[1], L. Dougherty-De Miguel[1], A. Bescós[1], J. A. Ramos-Quiroga[1], M. Loredo-Silos[1], I. Delgado-Álvarez[1] and G. Español-Martín[1]

[1]Hospital Universitari Vall d'Hebron, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.492

Introduction: Myoclonus-dystonia syndrome (MDS) is a rare childhood-onset movement disorder characterized by the combination of myoclonus and dystonia. It is caused by loss of function of the epsilon-sarcoglycan gene (*SGCE*) due to mutations, although the pathogenic mechanism is not fully understood. Deep brain stimulation is used in patients that are refractory to pharmacological treatment. A higher prevalence of psychiatric disorders has been observed in MDS patients, especially obsessive-compulsive disorder (OCD) (Timmers *et al.* Parkinsonism Relat Disord. 2019; 69 85-90). A dysfunction of cortico-basal ganglia-thalamo-cortical (CBGTC) loops is present in both conditions, but the mechanism by which they display high comorbidity is unknown.
Objectives: To determine the presence of OCD comorbidity in pediatric and young adult patients that are candidates for DBS treatment for motor disorders, and the effects that the treatment may have on OCD symptoms.
Methods: This study is part of an ongoing cohort (n = 34) of children and adolescents (at the time of diagnosis) receiving internal globus pallidus DBS as treatment for motor disorders in Vall d'Hebron Hospital. The candidates go through a psychiatric evaluation before the procedure, including the diagnostic interview K-SADS, to diagnose psychiatric comorbidity. Long-term evaluation is performed by subsequent visits to the specialist.
Results: Of the seven patients with *SGCE*+ MDS that underwent DBS treatment, four of them presented OCD symptoms before the procedure, two did not, and one did not receive an evaluation. Of the patients with OCD symptoms, all four of them showed significant improvement in motor function after DBS but had worsening of OCD symptoms. Some of the patients also had a worsening of other psychiatric symptoms, such as anxiety, mood and behavioral symptoms.
Conclusions: OCD symptoms are present in a significant proportion of our patients with *SGCE*+ MDS. OCD and other psychiatric symptoms worsened during follow-up in our patients, although it is not clear if this is due to DBS treatment or due to the natural course of the disorder. Further studies are needed to explore this observation.

Role of Naltrexone Plus Bupropion in Eating Behavior Adjustment: A Systematic Review and Meta-Analysis of Randomized Controlled Trials

D. F. Holanda[1]*, M. G. Ruelas[2], F. R. de Lima[3], G. H. S. da Silva[4], C. M. C. G. Q. Campos[4] and B. S. Pinto[1]

[1]Medicine, Federal University of Amazonas, Manaus, Brazil; [2]Instituto de Investigación Nutricional, Lima, Peru; [3]Independent practice, São Paulo and [4]Medicine, Catholic University of Pernambuco, Recife, Brazil

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.493

Introduction: Binge-eating disorder (BED) is a significant global health challenge associated with obesity and psychological issues. The combination of Naltrexone-Bupropion (NB) has emerged as a promising pharmacological approach for managing eating behaviors.
Objectives: This meta-analysis aims to evaluate the efficacy and safety of Naltrexone-Bupropion compared to placebo in managing eating behaviors, focusing on weight loss, binge-eating frequency, eating disorder psychopathology, quality of life, and adverse effects.
Methods: PubMed, Embase and Cochrane databases were searched for randomized controlled trials (RCT) comparing NB versus placebo for BED. Primary endpoints were weight loss and binge-eating frequency. Secondary endpoints included eating disorder psychopathology, depression, quality of life, food cravings, and adverse effects.The mean differences (MD) were applied with their 95% confidence intervals (95%CIs) for continuous outcomes, using a random-effects model. We used RevMan 5.4.1 for statistical analyses. Heterogeneity was assessed using the I^2 statistic.
Results: Five RCTs with 2,466 adult participants (mean age 46.5 years, BMI 21.5-50 kg/m^2) were included. NB was associated with a statistically significant reduction in weight loss percentage compared to placebo (MD -3.67%, 95% CI [-4.30; -3.03], I^2=98%; Figure 1). However, no significant differences were found between NB and placebo in reducing binge-eating episodes(SMD 0.02, 95% CI [-0.30; 0.34], I2 =0%, Figure 2) , improving eating disorder psychopathology, alleviating depression, or decreasing food cravings. Although NB showed some benefits in improving the quality of life, the results were not statistically significant. NB was associated with a higher risk of adverse effects, including nausea, headache, constipation, dizziness, vomiting, insomnia, and dry mouth. The certainty of the evidences is in the Summary of findings (SOF) of GRADE evaluation (Figure 3). After leave-one-out sensitivity analysis, no single study was found to influence the effect estimate or drive heterogeneity excessively.

Image 1:

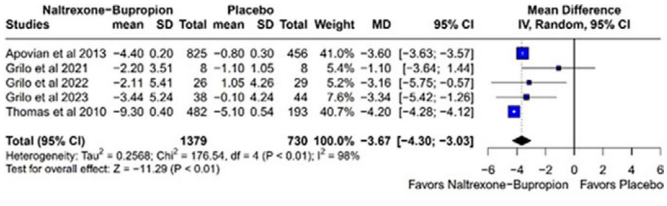

Figure 1 Forest plot of Naltrexone-Bupropion produces higher weight loss change (%).

Image 2:

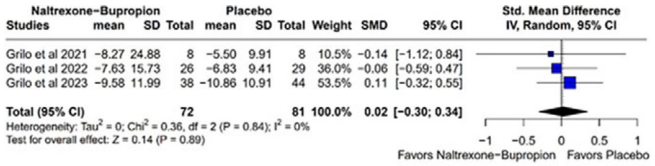

Figure 2 Forest plot of EDE Binge eating scores, no significant differences were found between NB and placebo in reducing binge-eating episodes.

Image 3:

Outcome	Risk difference with NB	95% CI	Nº of participants (studies)	Certainty of the evidence (GRADE)
Weight loss (%)	MD: 3.67 % lower	(-4.3 to -3.03)	2109 (5 RCTs)	⊕⊕⊕⊕ High
EDE Binge	SMD: 0.02 SD	(-0.30 to 0.34)	153 (3 RCTs)	⊕⊕◯◯ Low
EDE total	SMD: 0.11 SD	(-0.37 to 0.60)	153 (3 RCTs)	⊕◯◯◯ Very low
Depression	SMD: 0.08 SD	(-0.24 to 0.39)	153 (3 RCTs)	⊕⊕◯◯ Low
Food craving	SMD: 0.07 SD	(-0.46 to 0.31)	812 (3 RCTs)	⊕◯◯◯ Very low

Figure 3. Summary of findings (SOF) of GRADE evaluation.

Conclusions: NB demonstrated efficacy for weight loss in individuals with eating behavior issues but showed no significant benefits for core eating disorder symptoms. The higher risk of adverse effects necessitates careful consideration in clinical decision-making. Further research is needed to determine optimal patient populations, treatment duration, and strategies to mitigate adverse effects.

Social media influence on eating disorder: a pilot study

B. Morigine[1]*, G. Spennato[1], E. Scopetta[1], J. S. Napoli[1], A. Napoli[1], H. Lamberti[1], O. Scicolone[1] and F. Micanti[1]

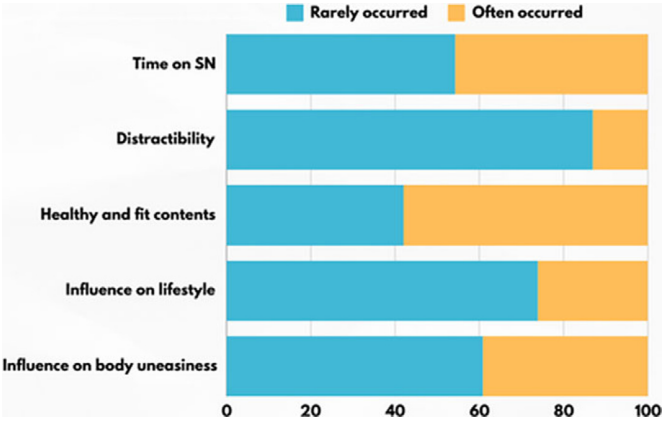
[1]UOC Psichiatria, Federico II, Napoli, Italy

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.494

Introduction: Eating disorders are a group of mental illnesses determining general health consequences. Several studies suggest that social media influence body image concerns, considered the core of eating disorder pathology. Thin idealization has become an increasing cultural focus, leading young people to pursue body image as a symbol of success.
Objectives: Aim of this study is to assess the quality and quantity of Social Network (SN) use and their influence on body uneasiness in individuals with Disordered Eating Behaviours (DEB) or Eating Disorders(ED)
Methods: 69 individuals suffering from Disordered Eating Behaviours (Grazing, Sweeteating, Food Addiction) or Eating Disorders (Night Eating Syndrome, Anorexia nervosa, Bulimia nervosa or Binge eating disorder) were enrolled. Mean age was 34 (SD ±11,33), mean BMI 28,68 (SD ±12,23). 93% of individuals were females. 20,29% (14) of the sample suffered from ED and 79,71% (55) from DEB. A social network self-administered questionnaire was used to

investigate which SN was most used and what contents were most shown in users' feed; domains investigated by the questionnaire are reported in fig. 1



Results: Questionnaire analysis allowed to investigate individuals preferences about social media use and the kind of contents they consumed the most. The data showed the most frequently used social network are Facebook (42%), Instagram (33%) and Tiktok (22%). Healthy and/or fit contents were frequently displayed on SN feed 57.9% (40), but only 26,08% (18) of users were influenced in their lifestyle and food habits. 39,13% (27) of the individuals also felt like this kind of contents increased their sense of body uneasiness.

The study emphasize that 42,85% of the individuals diagnosed with an ED answered that SN content influenced their lifestyle and 71,42% that it increased their feeling of body uneasiness. In individuals with DEB only 21,8% were influenced in their lifestyle and 30,9% describe a worsening of their body uneasiness, as is shown in Tab.1.

Tab 1

	Lifestyle and food habits	Body uneasiness	*N of individuals*
ED	42,85%	71,42%	14
DEB	21,8%	30,9%	55
ED+DEB	26,08%	39,13%	69

Image 1:

Conclusions: Social media contents about health, diet and sport impact on individuals body image, diet and body uneasiness, mostly in individuals diagnosed with ED. This evidence stresses the importance to take into account every component of ED and DEB for a global approach to individuals including an assessment on interests, hobbies and use of social media.

Prevalence of Avoidant/Restrictive Food Intake Disorder in Children Diagnosed with Autism Spectrum Disorder and Their Parents: A Study on the Broad Autism Phenotype

B. Ozel[1]*, S. Ceran[1], A. Bağcaz[1] and D. Kaba[2]

[1]Department of Psychiatry and [2]Department of Child and Adolescent Psychiatry, Baskent University, Ankara, Türkiye

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.495

Introduction: Avoidant/Restrictive Food Intake Disorder (ARFID) was introduced as a diagnostic category in DSM-5 to describe individuals with restrictive eating behaviors without fear of weight gain, differentiating it from Anorexia Nervosa (American Psychiatric Association, DSM-5, 2013). Although prevalent in children with Autism Spectrum Disorder (ASD), ARFID's co-occurrence with ASD and its prevalence in parents of children with ASD, particularly regarding the Broad Autism Phenotype (BAP), remains underexplored. This study investigates the prevalence of ARFID in both children diagnosed with ASD and their parents, focusing on BAP features in parents and their relationship with ARFID symptoms.

Objectives:

1. To determine the prevalence of ARFID in parents of children diagnosed with ASD.
2. To explore the relationship between ARFID symptoms and ASD symptoms in both parents and children, examining the role of BAP in parents.

Methods: A cross-sectional study was conducted at Başkent University Psychiatry Clinic. The sample consisted of 69 children aged 2-18 diagnosed with ASD and 115 parents. ARFID diagnosis was determined using structured clinical interviews and the Nine-Item ARFID Screen (NIAS), while autism symptoms were assessed using the Childhood Autism Rating Scale (CARS) for children and the Autism Spectrum Quotient (AQ) for parents. Psychosocial, anthropometric, and clinical assessments were performed, including body mass index (BMI), nutritional status, and vitamin deficiencies. Statistical analysis included t-tests, chi-square tests, and correlation analyses (SPSS 24).

Results: The study found that 34.8% of children with ASD (n=24) and 13% of parents (n=15) were diagnosed with ARFID, significantly higher than general population estimates (3.5%, $p<0.001$) (Thomas et al. Curr Psychiatry Rep 2017; 19: 54). Children with ARFID scored higher on the CARS (mean=38.58, SD=7.92) compared to non-ARFID children (mean=33.73, SD=5.59), with a statistically significant difference ($t=-2.878$, $p=0.005$). Furthermore, positive correlations were found between ARFID symptoms and autism-related features in both children and parents, particularly in the AQ imagination subscale ($r=0.358$, $p<0.01$).

Conclusions: This study highlights a significantly higher prevalence of ARFID in children with ASD and their parents compared to the general population. The strong correlation between ARFID

and ASD symptoms, particularly BAP features in parents, suggests shared neurodevelopmental pathways. These findings underscore the need for increased clinical awareness of ARFID in both ASD children and their families, as well as the importance of incorporating ARFID assessments into ASD treatment plans. Future research should focus on the genetic and developmental mechanisms linking ARFID and ASD.

The impact of viewing thinness and fitness transformation images on women's body dissatisfaction, weight management intentions, and emotions - an ecological momentary assessment study

S. Pan[1], X. Zeng[2], Y. Huang[3]*, Q. Sun[4] and J. He[4]

[1]Department of Psychiatry, The Chinese University of Hong Kong, Hong Kong, Hong Kong; [2]Department of Psychology, Central South University, Changsha, China; [3]Department of Psychology, The Chinese University of Hong Kong, Hong Kong, Hong Kong and [4]Department of Humanities and Social Science , The Chinese University of Hong Kong, Shenzhen, Shenzhen, China

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.496

Introduction: Transformation images, widely circulated on social media, depict a contrast between an 'unideal' body state and an 'ideal' one, often categorized under 'thinspiration' or 'fitspiration'. Unlike 'ideal' images shown individually, transformation images not only showcase an 'ideal' physique but also suggest its attainability. Although research has found that exposure to 'ideal' images is linked to risk factors for eating disorders, scant research has focused on the effects of transformation images.

Objectives: This study aims to investigate the impact of viewing transformation images on body dissatisfaction, weight management intentions, and emotions in adult young women.

Methods: 137 Chinese adult women (mean age 21.7±3.0 years) were randomly assigned to one of four image conditions: side-by-side thinness transformation images, side-by-side fitness transformation images, thinness images shown individually, and fitness images shown individually. After baseline assessment of Body Dissatisfaction, Body Mass Index, Internalization of Thinness/Muscularity, participants underwent a 7-day Ecological Momentary Assessment. Prompts were delivered four times per day at 3 to 4-hour intervals. Each prompt included the display of an image for 5 seconds, followed by a survey assessing body dissatisfaction, weight management intentions (intentions to diet, binge eating, and work out), and emotions (positive and negative emotions). Linear mixed models were used to analyze the data, controlling for baseline assessments, autocorrelation, and within-person variability.

Results: Fitness transformation images significantly increased intentions to diet ($p < 0.05$), binge eating ($p < 0.01$), and work out ($p < 0.05$) compared to fitness images shown individually (Table 1). However, this impact was not observed with thinness transformation images (Table 2). Neither thinness nor fitness transformation images had a significant impact on body dissatisfaction or emotions.

Baseline Body Mass Index	0.05	-0.06 – 0.17	0.345	-0.24	-3.32 – 2.83	0.876	0.98	-1.49 – 3.44	0.437
Baseline body dissatisfaction	0.01	-0.01 – 0.04	0.340	-0.82	-1.61 – -0.02	**0.044**	0.77	0.14 – 1.40	**0.017**
Internalization of thinness	0.45	0.13 – 0.77	**0.005**	2.44	-6.23 – 11.11	0.581	4.94	-1.99 – 11.87	0.162

Note: *b* = unstandardized regression coefficient, *CI* = confidence interval, **Bold** = statistically significant at $p < .05$.

Conclusions: Our study demonstrates that fitness transformation images have a stronger impact on weight management intentions than fitness images presented individually. This finding aligns with the cultural shift in the ideal of physical attractiveness, which now emphasizes 'fitness' and a 'healthy lifestyle' over 'thinness' in women. It is essential to focus on the exposure fitness transformation images on social media and to develop strategies for mitigating potential negative effects in the future.

doi: 10.1192/j.eurpsy.2025.497

Introduction: In high-income countries, Coordinated Specialized Care for First Psychotic Episode (FEP) programs have been shown to be effective in reducing symptoms and disability. Chile guarantees universal access to these services through a national policy, but previous research indicates that evidence-based approaches are not used. Our team adapted the OnTrackNY (OTNY) program to the Chilean context, called OnTrackChile (OTCH), to evaluate its effectiveness and implementation. This summary presents preliminary results on model fidelity, one of the primary outcomes of the study.
Objectives: To evaluate the fidelity of the implementation of the OTCH program in comparison with usual care services for FEP, analyzing its compliance in 18 key domains of care and its alignment with the National Mental Health Plan.
Methods: A fidelity scale was designed to guide data collection on OTCH implementation. The scale included the name and definition of each domain, along with a set of expectations. The scale assessed 18 key domains, such as staffing, team integration, communication, burden of care, service flexibility, crisis, treatment planning, prescribing, care management, working with families, and education and employment support, among others. The scale was applied in the 5 OTCH intervention sites and 8 control sites that maintained usual care included in the cluster-randomized controlled clinical trial.
Results: OTCH sites met more than 80% of the criteria for the domains assessed in the fidelity scale, which is more than twice the compliance observed in the control sites. In domains related to the usual functioning of the centers coincident with those established in the National Mental Health Plan, OTCH intervention sites exceeded compliance standards to control sites ($p<0.001$). In situations where the frequency of problems was similar between both types of centers, such as suicidal risk and risky substance use, OTCH centers showed significantly better performance ($p<0.001$) compared to control centers.
Conclusions: The implementation of the OTCH model has not only allowed the introduction of specific aspects of the program, but has also improved the overall performance of the centers in key areas defined by the National Mental Health Plan. This suggests that the implementation of OTCH in the Chilean context is not only feasible, but can also improve the quality of community mental health care.
OnTrack Chile is funded by the U.S. National Institute of Mental Health (R01MH115502).

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.498

Introduction: Capturing the complex and heterogeneous clinical phenotypes across Schizophrenia Spectrum Disorders (SSD) is still challenging and Artificial Intelligence is a promising tool. In the past years, machine learning (ML) models have been developed for diagnostic classification, highlighting both neuroimaging and language measures as relevant predictors (Zucchetti et al. It J of Psy (2024). Fewer studies focused on predicting symptom severity or quality of life, based on clinical variables, but with relatively low performance (Beaudoin, et al. Schizophrenia (2022); 8.1 29; Podichetty et al. Clin and Transl Sc (2021), 14(5), 1864-1874). However, to the best of our knowledge, no previous studies have applied ML regression tasks using neurophysiological features, nor combining them with language ones.
Objectives: The aim is to combine neurophysiological and language features via ML to predict symptoms severity in schizophrenia.
Methods: Forty-one individuals with a diagnosis of schizophrenia were enrolled and assessed for psychopathology, communicative-pragmatic abilities and underwent a 5-minute resting state EEG recordings.
A Least Absolute Shrinkage and Selection Operator (LASSO) regression was employed to identify significant EEG and language features, extracted through Natural Language Processing to predict symptoms severity. After feature selection, two LASSO models were built and compared: Model 1 (M1) included the most important EEG features, while Model 2 (M2) included both the most important EEG and language features.
Results: Feature selection led to the identification of main predictors, including EEG microstates and aperiodic activity, lexical-semantic features and imageability of words.
Both models reached an acceptable performance (MSE=0.590, adj. R^2= 0.344; MSE= 0.334, adj. R^2 =0.582), but the Diebold-Mariano test and BIC highlighted a significant difference between M1 and M2, indicating an improved performance in predicting symptoms, when adding language features. See Fig.1 for more details

Image 1:

Conclusions: These preliminary results identify relevant features, confirming the role of EEG and language measures as potential biomarkers for SSD. Innovatively, data also show that EEG variables alone, can reliably but only partially predict psychopathology, while the inclusion of linguistic variables further improves the model. Overall, EEG and language measures, obtained quickly through simple tasks, appear as relevant features that may discriminate clinical outcomes within SSD and implementation of ML tools mat help to guide diagnosis and refine treatments.

doi: 10.1192/j.eurpsy.2025.499

Introduction: This study explores whether high-dose treatment with SGA LAIs may benefit patients with schizophrenia who are inadequately controlled on a standard dose
Objectives: The objectives of this study have been to evaluate the retention, effectiveness and tolerability of high doses of second-generation antipsychotic long-acting injectable formulations (SGA LAI) in the treatment of patients with severe resistant schizophrenia.
Methods: A 72-month observational, mirror-image study of patients with severe (CGI-S ≥ 5) resistant schizophrenia receiving treatment with ≥75 mg of risperidone long-acting injectable (RLAI) (N = 60), ≥175 mg of monthly paliperidone palmitate (PP) (N = 60), and ≥600 mg of aripiprazole once-monthly (AOM) (N = 30). All of the patients were previously treated with at least two different APs, with poor outcomes. Patients were eligible if deemed likely to benefit from treatment with SGA LAIs: at risk of medication non-compliance, with a lack of effectiveness, or adverse effects with previous APs. The assessment included the CGI-S, the WHO-DAS, the Medication Adherence Rating Scale (MARS), laboratory tests, weight, adverse effects, reasons for treatment discontinuation, hospital admissions and suicide attempts.
Results: The average antipsychotic doses were: RLAI = 111.2 (9.1 SD) mg/14 days; PP = 231.2 (12.3 SD) mg eq./28 days; and AM = 780 (120 SD) mg/28 days.
Tolerability was good for all LAIs, reducing the side effects reported and the changes in biological parameters compared to previous treatments, especially in the AOM group. Weight and prolactin levels decreased in all LAI treatments; the reduction was statistically significant only among patients treated with AOM ($p < 0.05$). Two patients discontinued treatment due to side effects with AOM, five with PP and nine with RLAI .
There were four discontinuations with RLAI, two with PP, and one with AOM due to a lack of effectiveness. After three years, the scores decreased in CGI-S ($p < 0.01$) and in WHO-DAS in the four areas with all injectables. MARS increased with all LAIs ($p < 0.01$), especially with PP and AOM.
We report a statistically significant decrease in both hospital admissions ($p < 0.001$) and suicide attempts ($p < 0.001$) at the end of 36-month treatments, compared to the previous three years, without any difference across the three LAIs. In the previous three years, 60 patients discontinued their AP treatment, and 11 during the three-year follow-up ($p < 0.0001$
Conclusions: Our study indicates the good effectiveness and tolerability of RLAI, PP and AM at high doses. These SGA LAI treatments improved treatment adherence and outcomes of the patients, with good tolerability, helping them to achieve clinical stabilization and better functioning. Therefore, we suggest that, in some illness-critical conditions, high doses of SGA LAIs could represent an alternative to clozapine.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.500

Introduction: Psychosis is characterized by hallucinatory and delusional experiences. Although, it was mostly considered to be present among clinical populations, there is strong evidence it can also be found in the general population. Limited reviews currently exist on the quality of the assessment methods designed to evaluate psychotic-like experiences in the general population. None of them assessed whether the existing instruments measure the same construct and, consequently, neglected problems associated with the "jingle-jangle fallacy" (Weidman et al., 2017; Flake and Fried, 2020). This fallacy might account for contradictions in the literature, as well as, issues with generalizability of the results.
Objectives: The goal of our study is to better understand the agreement between various instruments used to assess hallucinations and paranoia-like experiences.
Methods: We conducted a systematic search of the scales assessing hallucinations and paranoia-like experiences among the general population. Labels for the content analysis were created based on their definition in literature by the first authors and revised by another researcher. Three researchers coded each item independently of each other. We then estimated to which extent any item overlaps with any item from the other scale included in the analysis. We used Jaccard index to assess similarities between sets (from 0 with no overlap among scales) to 1 (complete overlap). The analysis was done in R and Excel.
Results: For 263 items from 11 hallucination scales, we estimated 38 labels with a mean overlap of 0.19 (very weak). CAPS demonstrated the highest mean overlap of 0.26. The highest overlaps were observed between MUSEQ and CAPS (0.5), MUSEQ and SPQ (0.4), and between LSHS-R and RHS (0.4). For the paranoia scales, the analysis of 183 items drawn from 12 scales resulted in 18 labels. The mean overlap across these labels was 0.30 - a weak association. The PIQ exhibited the highest mean overlap at 0.42, whereas the PSQ displayed the weakest overlap with a value of 0.17.
Conclusions: The overlap between hallucination scales was very weak. This disparity may be due to different instruments adopt varying interpretations of the hallucination continuum (Laroi, 2012). The weak overlap in paranoia scales may be less problematic, as theoretical models and empirical data suggest a more clear continuum of suspiciousness within the general population (Freeman et al., 2005) that maps our results. It is necessary to establish certain common grounds regarding what experiences represent which sides of the continuum, both in their variability, and severity in the field.

From Gut to Mind: Microbiota's Impact on Schizophrenia

S. Hamzaoui[1]*, K. Mahfoudh[1], D. Mezri[1], U. Ouali[1], A. Aissa[1] and R. Jomli[1]

[1]Razi Hospital, Manouba, Tunisia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.501

Introduction: The human body hosts a vast array of commensal microbes known as the gut microbiota, which plays a crucial role in various physiological functions, including immune system maturation, digestion, and central nervous system development. Recent studies suggest a significant link between gut microbiota and psychiatric disorders, particularly schizophrenia. Imbalances in gut microbiota composition have been associated with symptom severity and treatment response in schizophrenia patients.
Objectives: This study aims to synthesize current knowledge on the role of gut microbiota in the severity of symptoms and the prediction of treatment response in schizophrenia, highlighting its potential as a biomarker for therapeutic strategies.
Methods: We conducted a systematic literature review following PRISMA guidelines, focusing on articles published between 2014 and 2024. Using databases like PubMed and Google Scholar, we searched for keywords related to gut microbiota, schizophrenia, first episode psychosis, treatment response, and symptoms severity.
Results: Our review included eight studies that utilized 16S rRNA sequencing to analyze fecal microbiota. The findings revealed significant correlations between specific gut microbiota profiles and the severity of psychiatric symptoms. Notably, families such as Lachnospiraceae and Bacteroidocacae were linked to increased symptom severity, while others, including Flavobacteriaceae, Enterococcaceae and Flintibacter butyricus , correlated with symptom remission. Additionally, variations in gut microbiota composition were predictive of treatment outcomes, suggesting its role as a potential biomarker for response to antipsychotic treatments.
Conclusions: The gut microbiota presents a promising avenue for understanding the complex interplay between microbial communities and psychiatric health. By identifying specific microbiota profiles associated with symptoms and treatment responses in schizophrenia, we can pave the way for novel personalized therapeutic approaches.

doi: 10.1192/j.eurpsy.2025.502

Introduction: Psychotic disorders, particularly schizophrenia, are severe mental illnesses associated with high rates of disability and functional impairment, causing significant individual burden and incurring high societal costs. Typical onset of schizophrenia is in late adolescence or early adulthood and the complex management requires often life-long pharmacological and non-pharmacological treatment. Early symptom recognition and timely intervention can improve the course of illness and result in better outcome and prognosis, effective management leads to a functional recovery. However, recent reports have identified significant gaps in access to timely assessment and shared decision-making interventions, with inadequate care pathways. In the face of an unprecedented demand for mental healthcare for young people, it can be challenging for health services to deliver high-quality mental healthcare which, according to the World Health Organization, should be timely, effective and evidence-based, safe and person-centered. The project covers nine countries in Europe.
Objectives: Building on the European Brain Council Rethinking Schizophrenia Beyond The Voices Policy Report (2024), the survey and literature review aim to: (1) evaluate the effectiveness of integrated models of youth mental healthcare on a broader range of outcomes, including both mental health outcomes, such as clinical symptoms, functioning and quality of life and health service outcomes, including access and satisfaction with care in young people; and (2) identify the common components of integrated care pathways for young people with first episode psychosis.
Methods: Using the care pathway as a tool at the first step of the research, a cross-country survey was co-designed with the Board of experts and anonymously launched earlier this year. By complementing the survey, the literature review on the care pathway will address quality and continuity of care from the first onset of psychosis and schizophrenia to long-term care in the selected countries including existing guidelines and overview country health situation assessments.
Results: Patients and mental health professionals' insights will be collected. Obtained data will also be analysed by the stakeholders and used to formulate recommendations for policy makers, care payers, mental health professionals, patients and their families (both country specific and at the EU level).
Conclusions: A policy report, based on the consensus, will be released at the Brain Awareness Week 2025 with results and recommendations which will provide valuable insight into understanding the needs of patients with first-episode psychosis and defining the optimal care pathways to engage with them. In order to show that there is a progress in the field of care for schizophrenia patients, the utilization of new technologies is included.

Oxytocin-augmented group psychotherapy for negative symptoms in patients with schizophrenia spectrum disorders – a study protocol

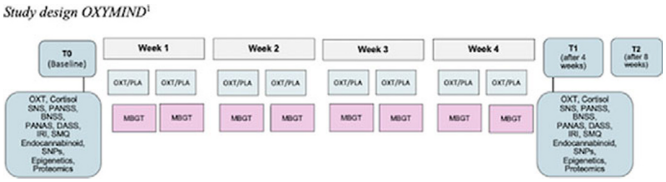
M. Zierhut[1]*, N. Bergmann[1], I. Hahne[1], J. Wohlthan[1], M. Bajbouj[1], E. Hahn[1] and K. Böge[1]

[1]Psychiatry and Neurosciences, Charite - Universitätsmedizin, Berlin, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.503

Introduction: New treatments for negative symptoms (NS) in schizophrenia spectrum disorders (SSD) are urgently needed. NS are believed to stem from disruptions between the mesocorticolimbic dopamine system and networks for socioemotional processes. Oxytocin (OXT) enhances connectivity between the neural networks, improving social cognition and NS. Lower plasma OXT levels are linked to greater NS severity and social cognition deficits in SSD. While OXT increases social cognition in healthy individuals, its effects in SSD are inconsistent. The social salience hypothesis suggests OXT's effect varies with social context. Our pilot study showed reduced NS with OXT administration in a positive social setting using mindfulness-based group therapy (MBGT).
Objectives: This trial aims to assess the effects of combining OXT with MBGT on each of the five NS in individuals with SSD. We hypothesize that OXT nasal spray administered before MBGT will significantly reduce NS compared to placebo. The primary outcome is the change in NS, measured by the Positive and Negative Syndrome Scale (T1 - T0 score difference) after 4 weeks and as secondary outcome on the Brief Negative Symptom Scale (BNSS) as well as changes of stress and affect.
Methods: The research design is a triple-blinded, randomized, placebo-controlled study comparing OXT to placebo. Manual-based MBGT sessions, led by experienced psychotherapists, occur weekly for four weeks with groups of up to six patients. Participants receive intranasal OXT (24 I.U.) or placebo 30 minutes before sessions, aligning with the peak effect window (30-80 min) for optimal social behavior reinforcement. Plasma oxytocin levels are measured by radioimmunoassay. Recruitment will be at the Department of Psychiatry, Charité, Berlin, including both genders in mixed-sex groups, controlling for contraceptive use and menstrual cycle phase. Nasal sprays are indistinguishable. The primary outcome will be analyzed using ANCOVA, with treatment condition and training group as covariates. Based on pilot and previous study effects, a conservative effect size of $f = 0.25$ is assumed. With 1:1 randomization, 80% power,

a 5% two-sided significance level, and a 10% drop-out rate, 140 subjects will be recruited.
Results: This project explores how OXT augmentation enhances the positive effects of MBGT. It is expected that combining OXT with MBGT will significantly improve NS, stress, and affect in SSD patients. Preliminary results already show a significant reduction in social withdrawal and blunted affect in the OXT group compared to placebo.

Image 1:



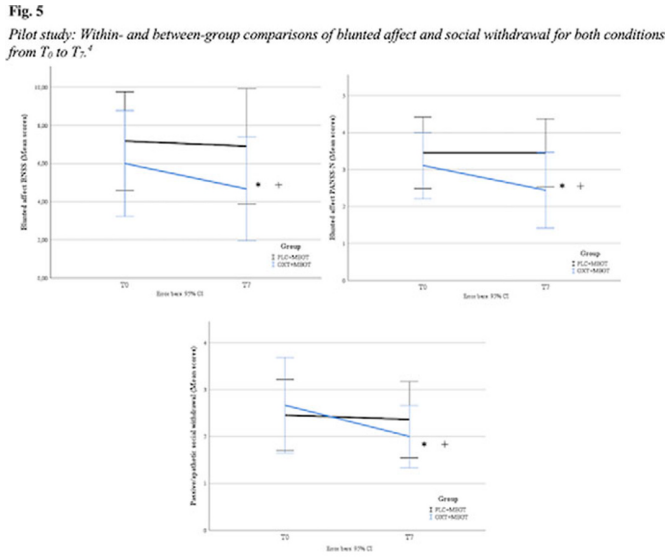


Image 2:

[3] *Note.* *$p < .05$= within group-changes using paired-samples t-tests; OXT: oxytocin; PLC: placebo; MBGT: mindfulness-based group therapy; PANSS-N: Positive and Negative Syndrome Scale – Negative Scale; BNSS: Brief Negative Symptoms Scale.
[4] *Note.* *$p < .05$= within group-changes using paired-samples t-tests; +$p < .05$= between-group changes as indicated by ANCOVA; OXT: oxytocin; PLC: placebo; MBGT: mindfulness-based group therapy; PANSS-N: Positive and Negative Syndrome Scale – Negative Scale; BNSS: Brief Negative Symptoms Scale; SNS: Self Evaluation of Negative Symptoms.

Conclusions: Current treatments for NS in SSD are insufficient, highlighting the urgent need for new or combined strategies. Evidence supports the benefits of augmented psychotherapy. This project could pave the way for innovative, personalized psychiatric treatment for SSD.

Persistent shorter and longer sleep duration from infancy to childhood and its prospective association with chronic depression symptoms

R. L. M. Amos[2], B. B. Durdurak[1], A. M. Gregory[3], S. Marwaha[2] and I. Morales-Muñoz[2*]

[1]Research & Development, Birmimgham and Solihull Mental Health Foundation Trust; [2]School of Psychology, Institute for Mental Health, University of Birmingham, Birmingham and [3]Department of Psychology, Royal Holloway University of London, London, United Kingdom

doi: 10.1192/j.eurpsy.2025.504

Introduction: Identifying early-life risk factors for chronic depression symptomology in young people, is essential to informing early targeted interventions. One highly prevalent symptom (and potential risk factor) in depression is sleep problems, such as insomnia or hypersomnia. However, most studies have measured sleep disturbances and depression symptoms at only one time point, and the prospective relationship between *persistent* shorter or longer sleep duration in childhood and *chronic depression symptoms* in adolescence through to adulthood has not been explored.
Objectives: To identify whether longitudinal trajectories of persistent shorter sleep and persistent longer sleep duration between 6 months to 7 years of age, are associated with increased risk of developing chronic depression symptoms between 13-22 years of age.
Methods: Prospective associations were explored using the Avon Longitudinal Study of Parents and Children (ALSPAC), in the UK. Childhood night-time sleep duration was parent-reported at 6, 18, and 30 months and at 3.5, 4 to 5, 5 to 6, and 6 to 7 years. Depression symptoms were self-reported via the Short Mood and Feelings Questionnaire (SMFQ) at, 12.5, 13.5, 16, 17.5, 18, 21 and 22 years of age. Latent Growth Curve Analysis was used to identify longitudinal trajectories of night-time sleep duration from 6 months to 7 years of age (i.e. longer (63%), shorter (2%), average-shorter sleep (22%) and average-longer sleep (13%)) and depression symptoms (i.e. chronic (5%), non-chronic (95%)) from 13 to 22 years. Logistic regressions were conducted to identify the prospective association between persistent shorter and persistent longer sleep trajectories and chronic depression symptoms.
Results: Preliminary results revealed that persistent shorter sleep duration across childhood was associated with increased likelihood of presenting with chronic depression symptoms, even after adjusting for the effects of sex, birthweight, maternal age, child ethnicity, family adversity and maternal socioeconomic status (OR = 1.94, 95% CIs, 1.01, 3.73 p =. 046). Persistent longer sleep however did not show significant associations.
Conclusions: A persistent pattern of shorter sleep duration across childhood is associated with chronic depression symptoms in adolescence through to adulthood. Sleep is a modifiable risk factor and targeted interventions for those presenting a sustained pattern of shorter sleep duration across childhood is suggested to prevent future mental health problems, such as depression.

Use of DORA Daridorexant for the deprescription of hypnotic medications for chronic insomnia comorbid with mood,anxiety and sedative hypnotic use disorders: a naturalistic longitudinal study

L. Anastasio[1]*, G. Alfi[2], G. Aquino[2], E. Annuzzi[1], G. Cerofolini[1], A. Coccoglioniti[1], M. Gambini[1], M. Pioltino[1], G. Perugi[1], A. Gemignani[1] and L. Palagini[1]

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.505

Introduction: Targeting insomnia may have a therapeutic value for mental disturbances. Indeed, insomnia chronic nature may necessitate switching between various insomnia approaches and medications. Daridorexant is a new *pharmacological option for insomnia treatment,* which is a *dual orexin receptor antagonist (DORA).*

Objectives: *The* aim of the present study was to treat consecutive patients with insomnia disorder with and without mental co-morbidities with this new therapeutic option and during the deprescripion of previous hypnotic medications which have failed in insomnia treatment.

Methods: Ninety consecutive patients with insomnia disorder according to the DSM-5-TR criteria (sleep condition indicator SCI<16) were treated with daridorexant 50 mg. Baseline, 1 month, and 3 month evaluations were performed. Demographic and clinical data were incorporated. Insomnia severity (Insomnia Severity Index-ISI), mood and anxiety symptoms (Beck Depression Inventory II-BDI-II, Young Mania Rating Scale-YMRS, Self Reported Anxiety Scale-SAS), and pre sleep arousal(Pre Sleep arousal Scale-PSAS) were evaluated. The evaluation of psychiatric diagnosis was conducted in accordance with the DSM-5-TR criteria (SCID-5) and the concurrent use of pharmacological therapy was taken into account. For previous insomnia treatment discontinuation, cross-tapered programs were developed following the 25% per week rule while inserting daridorexant.

Results: The final sample included 80 patients (N° 40, 50.0% females, mean age 60 ± 13.2). Most of them (75.5%) suffered from insomnia comorbid with unipolar/bipolar depression, anxiety disorders and sedative-hypnotics use disorders. Repeated Anova analyses showed that ISI and PSAS total score decreased across time (respectively F=63.42, p<0.001, F=61.44, p<0.001). Similarly mood symptoms, anxiety symptoms significantly improved over time and after 3 months of treatment (respectively F=62.45, p<0.001, F=31.48, p<0.001, F=41.14, p<0.001, F=21.44, p<0.001). Analyses conducted on a subsample of patients with comorbid sedative-hypnotics use disorders (50%) revealed a beneficial effect on insomnia, arousal and anxiety symptoms. Multiple regression models demonstrated that the clinical improvement of anxiety symptoms was most best predicted by the improvement in emotion regulation -PSAS score at T1 and T2, and the improvement in insomnia symptoms at T1and T2.

Conclusions: The treatment of chronic insomnia with daridorexant improved insomnia symptoms in patients with and without mental comorbidities across time. It was particularly effective in patients with sedative-hypnotics use disorders, where we deprescribed previous sedative hypnotics including neuroleptics and sedative antodepressants. These data are in line with the data showing that sleep is involved in the regulation of the reward system.

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.506

Introduction: Daridorexant is a dual orexin receptor antagonist approved for the treatment of chronic insomnia. Phase 3 studies have demonstrated that consistent nightly use of daridorexant 50 mg significantly improved both subjective total sleep time (sTST) and daytime functioning (Insomnia Symptoms and Impacts Questionnaire [IDSIQ] sleepiness domain) at Months 1 and 3 in patients with insomnia disorder versus placebo (Mignot *et al.* Lancet Neurol 2022; 21 125-39).

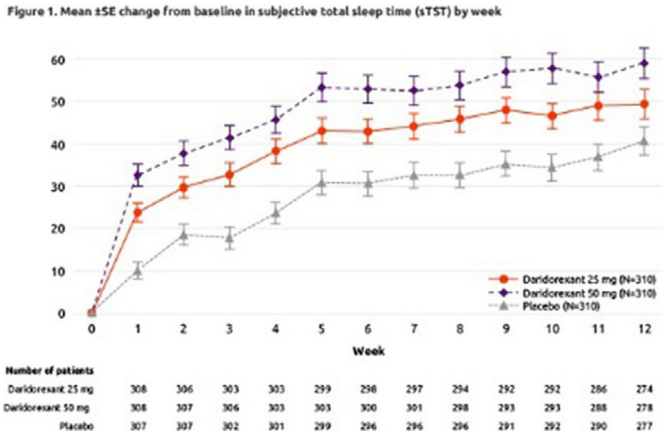
Objectives: This exploratory analysis evaluated how the effect of daridorexant on both sleep and daytime functioning are perceived by patients with insomnia over time (i.e. week by week), as compared to placebo.

Methods: In this multi-centre, double-blind trial (NCT03545191), adult (18–64y) and elderly (≥65y) patients with insomnia disorder were randomized (1:1:1) to receive daridorexant 25mg, 50mg or placebo every evening for 3 months. Patients completed daily eDiary entries throughout the study, and weekly mean changes from baseline in sTST and IDSIQ-sleepiness domain were used to assess patients' perceived duration of sleep and daytime functioning, respectively.

Results: Weekly mean changes from baseline of both the sTST (Figure 1) and IDSIQ-sleepiness domain (Figure 2) from Week 1 to Week 12 of treatment improved over time in all treatment groups. At each week, the observed improvements from baseline were numerically larger for daridorexant 25 and 50 mg than placebo, with the 50 mg group demonstrating the greatest response. For sTST, treatment differences versus placebo were seen from Week 1 of treatment (mean increases from baseline for 25 mg, 50 mg vs placebo of +23.83, +32.63 vs 10.07, respectively), and were maintained throughout the study. For IDSIQ-sleepiness domain scores,

treatment differences vs placebo were seen from Week 1 (mean reductions from baseline for 25 mg, 50 mg vs placebo of –1.56, –1.90 vs –0.92, respectively), with further separation from placebo until Week 4.

Image 1:



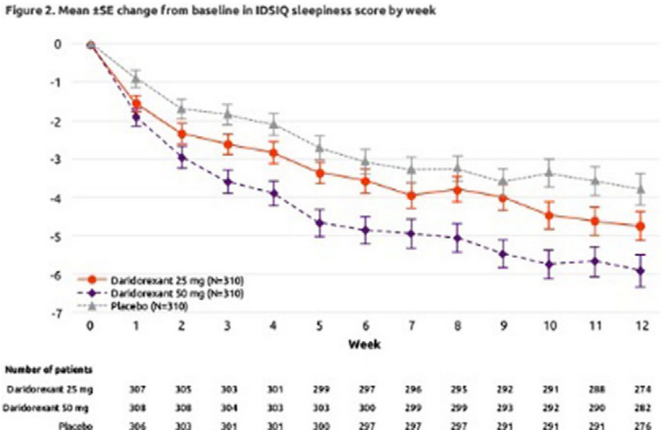


Image 2:

Conclusions: The benefits of daridorexant treatment on total time asleep and daytime functioning start to be perceived from Week 1. With consistent nightly use, efficacy on sleep and daytime functioning continued to build over the course of the 3-month treatment period, with the greatest effect being observed with daridorexant 50 mg.

Evaluation of an Enhanced Sleep Education Programme in Promoting Sleep and Circadian Health in Adolescents

A. H. Pang[1,2], W. Y. Chan[3]*, H. F. Sit[1], S. X. Li[1,4] and F. T. W. Cheung[1]

[1]Sleep Research Clinic and Laboratory, Department of Psychology; [2]School of Public Health, LKS Faculty of Medicine, The University of Hong Kong; [3]Department of Psychology, The Education University of Hong Kong and [4]The State Key Laboratory of Brain and Cognitive Sciences, The University of Hong Kong, Hong Kong, China
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.507

Introduction: Sleep problems, particularly insomnia and sleep deprivation, are common among adolescents, and may increase their risk for poor psychosocial and metabolic health. Traditional classroom-based education programmes showed inconsistent results in promoting sleep behavioural changes. In contrast, enhancing training programme with experiential activities alongside classroom learning may be considered as a more sustainable means to promote healthy sleep in adolescents.
Objectives: The present study evaluated the impact of a four-week enhanced sleep education programme on adolescents' sleep quality, knowledge and behaviour, and their experience of participation.
Methods: Adolescent participants took part in the Youth Sleep Ambassadors Programme, which was designed to equip them with evidence-based information on sleep and circadian health through active learning and community outreach activities. A mixed-methods design was adopted to evaluate the programme. Participants completed self-administered questionnaires, including a sleep knowledge quiz, the Pittsburgh Sleep Quality Index (PSQI) to assess subjective sleep quality, and the Sleep Hygiene Index (SHI) to evaluate healthy sleep behaviour, before and after the programme. Additionally, two focus groups were conducted to understand participants' experiences with the programme.
Results: Thirteen participants, aged 15 to 17, participated in the progamme and rated the programme's effectiveness at 4.38 out of 5. At post-programme, there were significant increases in total sleep time (baseline: 6.12hr, post: 7.31hr, p=.006) and time in bed (baseline: 6.83hr, post: 7.98hr, p=.046), in addition to a reduction in PSQI score (baseline: 5.92±1.98, post: 3.92±1.50, p=.031). There was a noticeable trend of improved sleep knowledge with a 13.5% increase in correct rate and healthy sleep behaviour (SHI: baseline: 24.4±6.76, post: 20.6±5.33). Focus groups revealed increased awareness and confidence to advocate for better sleep and mental health among peers. Participants praised the programme as professional and well-organised but expressed a preference for more experiential and research activity over classroom learning, underscoring the limitations of classroom-based sleep education.
Conclusions: The findings provided preliminary support for this enhanced sleep education programme as a viable strategy to engage

adolescents in understanding and awareness of sleep and circadian health. Beyond traditional classroom education, self-discovery and knowledge application with experiential tasks can better develop their perspectives and advocate in their community.

Effectiveness of EMDR Therapy on Cognitive Performances in Patients with Post-Traumatic Stress Disorder and Complex Post-Traumatic Stress Disorder: A 6-Month Follow-Up Study

T. B. Jannini[1]*, L. Longo[2], R. Rossi[2], M. Gagliano[2], A. Pompeo[2], A. Di Mario[2], C. Niolu[2], A. Siracusano[2] and G. Di Lorenzo[2]

[1]Department of Experimental Medicine and [2]Department of Systems Medicine, Tor Vergata University of Rome, Rome, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.508

Introduction: Complex post-traumatic stress disorder (cPTSD) is a clinical entity characterized not only by the typical symptoms of hyperarousal, avoidance, and flashbacks but also by disturbances in self-organization. Given the well-known association between trauma and cognitive deficits, it is common to observe a significant prevalence of such alterations among patients with cPTSD.
Objectives: The aim of this study is therefore to assess cognitive functioning in response to treatment using Eye Movement Desensitization and Reprocessing (EMDR).
Methods: Fifty-eight patients were recruited and divided into two groups (28 PTSD; 23 cPTSD), to whom scales for post-traumatic symptomatology (Impact of Event Scale – revised – IES-R; Clinician-Administered PTSD Scale – CAPS), along with cognitive tests (MATRICS Consensus Cognitive Battery - MCCB), were administered. The patients were evaluated at baseline (T0) and 6 months after the completion of the last EMDR session (T6).
Results: EMDR was effective in the treatment of post-traumatic symptomatology (IES-R; CAPS - $p<0.001$). The PTSD group showed improvement in the domains of verbal learning (RAVLT), visual attention (TMT-A), and working memory (CBTT) ($p<0.05$). The cPTSD group reported improvement in the verbal learning domain ($p<0.05$).
Conclusions: In addition to clinical symptomatology, EMDR has been shown to be effective in treating cognitive deficits in patients with PTSD and cPTSD. However, further studies are needed to confirm the results and identify the underlying mechanisms of this effect.

Nightmares and childhood trauma in depression and insomnia among adolescents: A pilot study

Y. Li[1]*, H. F. Sit[1], Y. L. Wong[1] and S. X. Li[1,2]

[1]Department of Psychology and [2]The State Key Laboratory of Brain and Cognitive Sciences, The University of Hong Kong, Hong Kong, Hong Kong
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.509

Introduction: Nightmares have been linked to childhood trauma and an increased risk for mental health problems, such as depression. Meanwhile, there is a high comrobdity of nightmares and insomnia. Yet relatively few studies have compared the clinical presentations of nightmares in different clinical groups. Additionally, considering the close association between childhood trauma, insomnia, and depression, there might exist potential unique interactions between childhood trauma and clinical diagnoses on nightmare experience.
Objectives: This case-control study aimed to compare nightmare-related parameters (i.e., frequency, distress, severity, and impairment), and childhood trauma among adolescents with depression only (DG), insomnia only (IG), and healthy control (HG) groups. We explored the interaction between diagnosis and childhood trauma on nightmare parameters.
Methods: Participants completed a clinical interview to ascertain their eligibility. Data on demographic and clinical information, childhood trauma as assessed by the childhood trauma Questionnaire (CTQ) , and nightmare-related parameters, including nightmare frequency, nightmare distress, nightmare severity, and nightmare impairment, were analysed in the current study. Analysis of variance (ANOVA) and multivariate analysis of variance (MANOVA) were used to examine the group differences, and regression analysis was used to examine the interaction effect on study variables.
Results: Adolescents with insomnia ($N = 31$; age 16.84 ± 1.88 years; female: 54.8%), female: 55.2%), depression ($N = 22$; age 17.50 ± 2.18 years; female: 54.5%) and healthy controls ($N = 31$; age 16.84 ± 1.88 years; female: 54.8%) were recruited. Compared to the HG, the IG and DG had greater nightmare distress (IG: $p = .024$; DG: $p = .005$) and nightmare impairment (IG: $p = .007$; DG: $p = .031$), but not nightmare frequency. However, only DG showed significantly higher nightmare severity ($p = .038$). No other significant differences were found in nightmare parameters between IG and DG (all $p > .05$). For childhood trauma, only DG showed significantly higher scores in emotional abuse ($p = .013$), emotional neglect ($p = .021$), and physical neglect ($p = .012$). No interaction effect of childhood trauma and clinical diagnosis was found on nightmare-related parameters (all $p > .05$).
Conclusions: This study showed that adolescents with insomnia or depression exhibited greater nightmare-related distress and impairment. Higher nightmare severity may be a unique characteristic in adolescents with depression but not for insomnia. Despite the depression group reporting significantly more childhood traumatic experiences, the potential interaction effect between diagnosis and childhood trauma was not observed on nightmare-related parameters. Future research may examine the relationship between the relevant variables in a larger sample size using a longitudinal design.

Acupuncture in trauma-related disorders – the novel treatment approach with acupuncture-based exposition (ABE) method

A. Sobieraj Bunse[1,2]*, J. Schottdorf[3] and R. Musil[1,2]

[1]Ludwig Maximilian Universität, Munich; [2]Privatklinik Oberberg, Bad Toelz and [3]Private Practise, Friedberg, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.510

Introduction: The evaluation of trauma-related disorders is becoming increasingly significant in psychiatric assessments. According to the DSM-5, these disorders are categorized as Post-Traumatic Stress Disorder (PTSD), Acute Stress Disorder, Adjustment Disorders, Prolonged Grief Disorder, Reactive Attachment Disorder, and other specified trauma- and stressor-related disorders. International guidelines on post-traumatic symptoms report positive outcomes with trauma-focused cognitive-behavioral therapy and EMDR, as well as non-trauma-focused therapies, such as relaxation techniques. Acupuncture and acupressure techniques can be used not only for treating symptoms but also for addressing associated sleep disorders, headaches and affective disorders. These methods are clinically applied to patients with traumatic events, primarily as ear acupuncture using the NADA protocol, along with 'Battlefield Acupuncture,' which has been established among American soldiers. In our clinical work, we use a unique protocol called Acupuncture-Based Exposition (ABE) (Schottdorf & Musil, 2017).
Objectives: The assessment of the effectiveness of the newly developed method of Acupuncture-Based Exposure (ABE).
Methods: The ABE (Acupuncture-Based Exposition) method was developed by Dr. Schottdorf and investigated by Dr. Musil and has already been clinically applied in their practice and clinic to a variety of patients. It has also been invetigated in an initial pilot study focusing on Type I trauma-related disorders, post-embitterment disorder as well as postpartum depression, and pain disorders. During ABE sessions, after a basic acupuncture treatment, patients are guided to visualize images of their traumatic experiences. The resulting physical sensations and emotions are addressed through corresponding acupuncture points until their intensity decreases. Finally, the imagined images are faded out using points on the head. Patients subsequently report a significant reduction in the burden of intrusive memories.
Results: In an initial case series involving 24 patients with trauma-related symptoms, an average reduction in trauma-specific symptoms was observed after just 3.95 sessions, as measured by the Impact of Events Scale-Revised (IES-R), from 55.6 ± 23.0 to 16.2 ± 21.1 (Wilcoxon test: $p < 0.002$). Additionally, a decrease in depressive symptoms was noted, measured by the Beck Depression Inventory, from 38.3 ± 8.0 to 25.6 ± 8.0 (Wilcoxon test: $p < 0.001$) (Schottdorf, 2018). So far, there have been no investigations into the mechanisms of action of ABE beyond clinical experience and initial data from clinical pilot projects.
Conclusions: Particularly, integrating acupuncture as an adjunct to conventional treatments for mental disorders appears to offer promising results. Further clinical research in the field of acupuncture and the ABE method is necessary.

doi: 10.1192/j.eurpsy.2025.511

Introduction: Daridorexant, a dual orexin receptor antagonist [DORA] which works by selectively reducing the orexin-induced wake signalling, has been shown to induce a dose-dependent reduction in wake time after sleep onset [WASO] in patients with insomnia disorder (Dauvilliers et al. Ann Neurol 2020; 87 347–356).
Objectives: This exploratory analysis examined the efficacy of daridorexant in reducing the duration of awakenings in each quarter of the night, when compared to placebo and to the GABA-receptor agonist zolpidem, which induces sleep through widespread CNS sedation.
Methods: This was a multi-centre, double-blind trial (NCT02839200), including adult (18–64y) patients with insomnia randomized (1:1:1:1:1:1) to placebo, daridorexant (5, 10, 25, or 50mg), or zolpidem (10mg) for 30 days. Polysomnography [PSG]-determined WASO was evaluated using descriptive statistics by quarter of the night (Q1–Q4) i.e. every 2 hours over 8 hours at Days 1 & 2, 15 & 16, and 28 & 29. Baseline was defined as the mean of the two PSG nights during the run-in period and Days 1&2 as the mean of the first two PSG treatment nights; Days 15&16 and 28&29 were defined similarly.
Results: Dose-dependent decreases in mean change from baseline in Q1–Q4 WASO were observed with daridorexant (5–50mg) at Days 1 & 2 (**Figure 1**). Whereas the approved doses of daridorexant (25mg and 50mg) provided similar response to zolpidem 10mg in the first half of the night, mean reductions from baseline in WASO were numerically greater with daridorexant 50mg versus zolpidem 10mg during the second half of the night – with the difference most pronounced in the fourth quarter (mean WASO change from baseline Q3: –13.49 min versus –9.73 min; Q4: –17.51 min versus –7.81 min). Similar effects were seen at Days 15 & 16, and Days 28 & 29.

Image 1:

Conclusions: In patients with insomnia disorder, daridorexant reduces the duration of awakenings throughout the entire night, including the last two quarters.

Genome-wide DNA methylation in Human Brain and Molecular Pathologies associated with Suicide Among Depressed Patients

Y. Dwivedi

Psychiatry, University of Aalabam at Birmingha, Birmingham, United States
doi: 10.1192/j.eurpsy.2025.512

Introduction: Major depressive disorder (MDD) is the single most important risk factor for suicide. Interestingly, even with a high prevalence of suicidality, not all MDD patients develop suicidal thoughts or complete suicide. Thus, it is critical to examine the risk factors that can distinguish suicidality among MDD patients.

Objectives: It has been hypothesized that epigenetic marks, such as DNA methylation, can be influenced by the environment, which may play a critical role in developing depression and suicidal behavior. The present study examined genome-wide DNA methylation in the prefrontal cortex of depressed suicide (DS), depressed non-suicide (DNS), and nonpsychiatric control subjects.

Methods: Genome-wide DNA methylation was examined in the prefrontal cortex of age- and sex-matched depressed suicide, depressed non-suicide, and nonpsychiatric control subjects using 850K Infinium Methylation EPIC BeadChip. The methylation β values were generated based on normalized signal intensities and background subtraction using negative control probes and were derived as the ratio of methylation probe intensity to the overall intensity. The hyper and hypo-methylated sites were also mapped across 22 autosomes using PhenoGram Plot. The significantly differentially methylated gene lists were used to determine the functional enrichment of genes for ontological clustering and pathway analysis.

Results: The chromosome-wise methylation sites and mapping of methylated sites based on the number of CpG content and their relative distribution from specific landmark regions of genes identified 32958 methylation sites 12574 genes in NC vs. all MDD subjects, 30852 methylation sites across 12019 genes in NC vs. DNS, 41648 methylation sites across 13941 genes in NC vs. DS, and 49848 methylation sites across 15015 genes in DNS vs. DS groups. A comparison of methylation sites showed 33129 unique methylation sites and 5451 genes in the DNS group compared to the DS group. Functional analysis suggested Oxytocin, GABA, VGFA, TNFA, and MTOR pathways associated with suicide in the MDD group.

Conclusions: Our data show a discrete pattern of DNA methylation, the genomic distribution of differentially methylated sites, gene enrichment, and pathways in MDD subjects who died by suicide compared to non-suicide MDD subjects and suggest that epigenetic DNA modifications could be used to distinguish suicidality in MDD patients.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.513

Introduction: Psychiatric disorders are risk factors for suicidality, but it is also considered a multifactorial phenomenon. Genome-wide association studies may provide an insight into the etiological background of distinct phenomena along the suicidal continuum,

and may also help disentangle their overlapping genetic architecture with psychiatric disorders.
Objectives: Our aim was to carried out a GWAS for suicidal ideation in a well-phenotyped sample.
Methods: We conducted a genome-wide association study (GWAS) in the NewMood (New Molecules in Mood Disorders, Manchester and Budapest) database, 1820 subjects were involved (533 males, 1287 females), the suicidal ideation and behaviour were investigated with a suicide-focused item of the Brief Symptom Inventory (BSI). SNP-level association was assessed employing linear regression models, assuming additive genetic effects, using PLINK2.0, with gender, age and the first ten principal components (PCs) of the genetic data as covariates. Bonferroni-corrected significance threshold on SNP-level was $p \leq 5.0 \times 10\text{-}8$, and the suggestive significance threshold was $p \leq 1.0 \times 10\text{-}5$. GWAS results including the identified significant results were interpreted using FUMA v1.5.2.
Results: 9 SNPs were identified, 2 with genome-wide significance and 7 with suggestive significance. The most significant SNP, *rs79912020* (β=, P=3.21x10^{-10}, Chr4) was located in the *MANBA* gene and the other genome-wide significant variant, rs10236520 (β=, P= 1.706x10^{-8}, Chr7) is located near the gene *LOC124901613*. Furthermore, we have found more important variants with suggestive significance, rs117677616 (β= , P=1.199x10^{-6}, Chr20) is identified in *PTPRT* gene, rs34475 (β= , P=1.981x10^{-6}, Chr12) is located in *CFAP54*, rs711180 (β= , P= 2.934x10^{-6}, Chr12) is near the gene *VWA1* and the variant rs2655484 (β= , P=5.717x10^{-6}, Chr12) is located near the *GRIP1*. No genes were identified in gene-level analysis with genome-wide significance.
Conclusions: We identified 9 SNPs with genome-wide or suggestive significance in association with suicidal ideation, with several lines of converging evidence supporting their involvement in the development of suicide risk. *MANBA* gene has role in the development of unipolar depression, *PTPRT* is associated with appearance of major depressive disorder, and the *GRIP1* gene may be considered also as a potential biomarker for suicide, as it has been previously associated with psychiatric phenotypes indirectly linked to suicidal behaviour and in patients with increasing suicidal ideation during antidepressant treatment. The prevention of the suicides is a prominent aim in mental healthcare and these new variants may be helpful in establishing novel, focused and more filters for this vulnerability.

doi: 10.1192/j.eurpsy.2025.514

Introduction: Suicide is a global health issue. Clinicians still have difficulties to differentiate patients who will or not commit suicide. This process is influenced by emotional and rational factors. Emotional responses (also known as countertransference) refers to what emotions clinicians experience. When working with suicidal patients, clinicians frequently experience negative emotions, such as fear, guilt and hopelessness. Clinicians' negative emotions responses contribute to their assessment of risk. Possible factors that influence emotional responses are myths and beliefs around suicide, contributing to stigma.
Objectives: This study aims to investigate the relationship between emotional responses, knowledge and stigma about suicide when providing care to suicidal patients.
Methods: An anonymous web-based survey was implemented through the software REDCap. Data were collected by snowball sampling. Participation was voluntary and participants had the ability to opt out at any time. The study was approved by the University Ethics Committee. The survey consisted of the Informed Consent Form (ICF), Sociodemographic Questionnaire, Scale of Myths, Beliefs and Attitudes About Suicide (SMBAS) - which evaluates stigma about suicide trough true or false questions. We also included the Rating Scale for Countertransference (RSCT) which evaluates the main emotional responses towards suicidal patients, divided in approach, indifference or rejection. Other questionnaires were included for future research, beyond the scope of this study.
Results: From 210 respondents, 179 (85.2%) completed the questionnaire. Sociodemographics: 108 (60.3%) were female; 166 (92.7%) were self-declared white-colored skin; The mean age was 37.22 (*SD* = 12.33), with 6 (0 to 48) median years of professional life [65(36.3%) were medical residents; 112(62.6%) were already specialists, 54(48.2%) of those declared to be psychiatrists]. Psychiatrists had highest rate of correct answers (M = *28,96*, SD = 1,84) in SMBAS when compared with non-psychiatrists (M = 27,86, SD = 2,39 , p = 0,008); Psychiatrists presented more emotional responses of interest (M = 2,58, SD 0,68, $p < 0{,}001$), solidarity (M = 2,81, SD 0,45, $p < 0{,}001$) and desire to help (M = 2,83, SD 0,38, p = 0,010). Non-psychiatrists presented more emotional responses of hostility (M = 0,06, SD 0,25, p = 0,040) and distance (M = 0,32, SD 0,56, p = 0,002). Psychiatrists presented more approach (p=0,03) and non-psychiatrist indifference (p=0,03).
Conclusions: We find preliminary evidence that psychiatrist present higher knowledge around suicide theme, having lower stigma around suicide. Psychiatrists also present more countertransference of approach and less of indifference.

Severe Personality Disorder with Chronic Suicidal Ideation Treated through an Intensive Acute Care Program

T. Bollain Muñoz[1], I. Oliveira Amat[1*], M. Valtueña Garcia[2], M. L. Barrigón Estevez[2], J. Sanchez Adsuara[2] and R. Crespo Rubio[1]

[1]Psychiatry and [2]HGUGM, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.515

Introduction: 34-year-old patient with multiple sporadic and brief contacts with mental health services, which he unilaterally chooses to discontinue. He has a long history of parasuicidal behavior dating back to adolescence. The patient does not report any prior diagnoses and has no history of inpatient admissions. The patient describes experiencing social isolation, lacking contact with his family of origin, and having no significant peer relationships.
Objectives: The primary goal is to improve the patient's engagement with mental health services, particularly in a case experiencing chronic, unaddressed symptoms, by utilizing intensive and structured programs. An additional objective is to address the patient's self-identification with suicidal ideation.
Methods: The patient's first contact with mental health services in this region of Spain was through the emergency department following a suicidal episode. During this encounter, the clinician introduced an intensive program designed to address suicidal ideation through regular visits over a set period. The patient agreed to participate and was subsequently enrolled in the PRISURE program at HGUGM in Madrid, where he received multiple sessions each month (between 2 and 4) with both a psychiatrist and a nurse from March to June 2024.
Results: At the beginning of the program, the patient was fixated on the idea of suicide from a romantic/nihilistic perspective, displaying a pervasive rejection of interpersonal contact and a narcissistic element in interactions. He expressed persistent suicidal ideation. Over the course of frequent visits, the patient gradually began to connect with the chronic nature of his behaviors and started to identify additional symptoms. Despite partial engagement in the program, in this case with some missing consultations, his attendance at consultations improved significantly compared to his prior behaviors. An inpatient stay was initially offered and declined by the patient; however, after further consideration, he later presented to the emergency room and agreed to inpatient treatment. During the admission, a diagnostic assessment was carried out and discussed with the patient, revealing challenges in identity, object relations, and moral functioning, which were positioned within the spectrum of personality disorders, particularly highlighting narcissistic and antisocial traits.
Conclusions: Initially focused on his suicidal ideation, the patient, through the PRISURE program, gradually explored underlying difficulties contributing to his suicidal behavior. This process allowed him to accept further support, ultimately leading to an inpatient stay. Potential diagnoses were discussed openly with the patient, helping him to gain a clearer understanding of his lifelong challenges and enabling him to articulate these difficulties within the therapeutic context.

doi: 10.1192/j.eurpsy.2025.516

Introduction: Inspired by discussions at the EPA Summer School 2024 on suicide prevention, this poster explores local strategies implemented across European nations. Emphasizing the importance of tailored approaches, the study analyses successful initiatives and community-based programs, and investigates how country-specific factors influence suicide rates. Key findings from research papers on innovative methodologies were also examined, offering insights to inform future practices in suicide prevention.
Objectives: The poster aims to:

- Present local strategies for suicide prevention across European countries, focusing on the contributions of clinicians who attended the EPA Summer School.
- Highlight how knowledge of diverse strategies can impact clinical practice in mental health across Europe.

Methods:

- **Categorization:** European countries are grouped by suicide rates—high, medium, and low—using WHO and European CDC data.
- **Summarization:** Local prevention strategies and programs in each group are summarized.
- **Analysis:** Various socio-economic and cultural factors influencing suicide rates are discussed, including stigma, economic conditions, and access to healthcare.
- **Comparative Approach:** Strategies are compared to identify common successful elements and contextual challenges.

Results:
Conclusions: Local strategies tailored to national contexts are essential in suicide prevention efforts. Comparing diverse strategies reveals that approaches addressing cultural and economic factors hold the most promise for reducing suicide rates across Europe. This analysis underscores the need for continued cross-border collaboration and the exchange of best practices to create more effective, context-specific interventions.

Suicide risk after discharge from in-patient psychiatric care: A 15-year retrospective cohort study of individual patient data

A. Trojer[1]*, D. König-Castillo[1], A. Gleiss[2], B. Vyssoki[1], M. Grömer[1], S. Weber[1], A. Glahn[3], L. Sommer[1], C. Harrer[1], S. Listabarth[1] and A. Wippel[1]

[1]Clinical Division of Social Psychiatry, Department of Psychiatry and Psychotherapy; [2]Institute of Clinical Biometrics, Center for Medical Data Science, Medical University of Vienna, Vienna, Austria and [3]Department for Psychiatry, Social Psychiatry and Psychotherapy, Medical University of Hannover, Hannover, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.517

Introduction: Suicide remains a leading cause of death worldwide, representing a significant public mental health challenge across all populations. Moreover, suicide rates are notably higher in patients following discharge from inpatient psychiatric care. Existing evidence regarding the specific risk factors for suicide in this population, however, remains contradictory. This study aims to systematically investigate those risk factors for post-discharge suicide death from a large psychiatric care facility.
Objectives: To identify the risk factors associated with suicide following discharge from psychiatric care.
Methods: Data from a 15-year single-centre cohort study were linked with national death registry records. Competing risk models were employed to calculate cumulative incidence rates. Key variables analyzed included sex, age at admission, discharge diagnosis, year of admission and length of stay. Subdistribution hazard ratios for these factors were computed using Fine-Gray models.
Results: In the sample of 18,425 discharges from 10,973 individual patients (57.03% female), a relative excess hazard to die by suicide of 1.4 additional suicides per 100,000 population the first year after discharge compared to the general population was found. That risk of suicide after discharge was significantly higher for males (SHR = 1.67; p = 0.037) as well as for patients diagnosed with affective disorders (SHR = 3.56; p = 0.017) and neurotic stress and somatoform disorders (SHR = 3.73; p = 0.024). The risk of suicide decreased significantly in more recent discharge periods (SHR = 0.93; p = 0.006). The length of hospital stay did not show a statistically significant association with suicide risk (SHR = 0.98; p = 0.834).

Image 1:

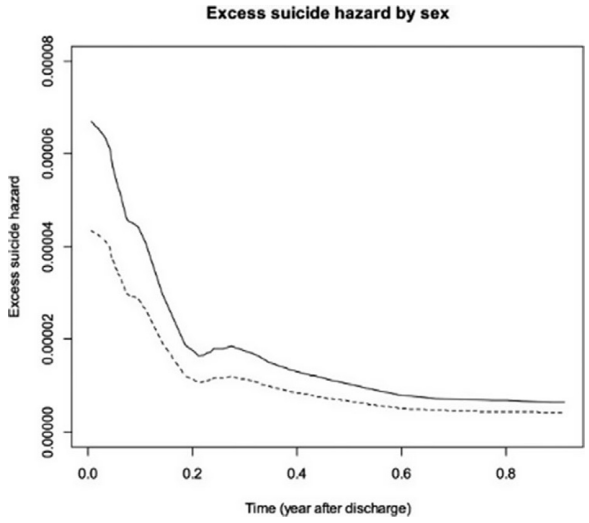

Image 2:

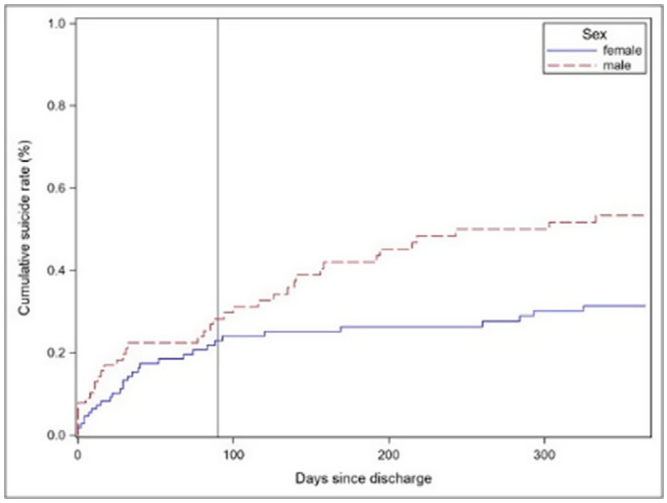

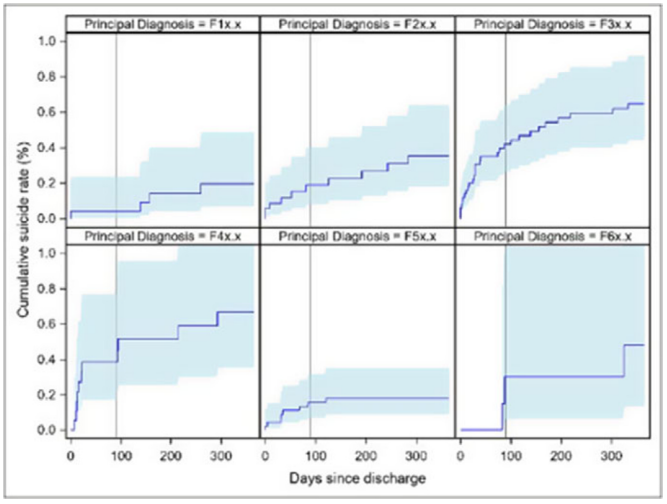

Image 3:

Conclusions: Male sex and specific diagnoses, notably affective and neurotic stress and somatoform disorders, were associated with an increased risk of suicide following discharge from psychiatric care. The observed decrease in risk over time could potentially point to improvements in post-discharge patient management and or treatment. These findings underscore the necessity for enhanced risk assessment tools and targeted interventions to address suicide risk in discharged psychiatric patients.

Good News? Assessing Time-Trends in Fidelity to Responsible Reporting of Suicide Guidelines in the Canadian News Media from 2019-2023

R. Whitley[1]* and J. Careau[2]

[1]Psychiatry, McGill University and [2]Psychiatry, Douglas Research Centre, Montreal, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.518

Introduction: Research indicates that detailed and sensational media coverage of suicide can contribute to suicide mortality, known as the Werther Effect. Other research indicates that responsible reporting of suicide can promote hope and resilience, which can reduce suicidality, known as the Papageno effect. This has led to the development of responsible reporting of suicide guidelines. In Canada, these are contained in a booklet called *Mindset,* which was co-created by journalists and mental health experts. *Mindset* lists bullet-pointed recommendations for journalists, and has been widely disseminated to newsrooms, journalism schools and media professionals across the country, in tandem with educational activities aimed at journalists by suicide prevention experts.
Objectives: The overall aim of this study is to assess fidelity to *Mindset* responsible reporting of suicide guidelines in the Canadian media over a multi-year period. A secondary objective is to assess whether fidelity to responsible reporting of suicide guidelines during the COVID-19 pandemic was significantly different to pre/post pandemic reporting of suicide.
Methods: We collected articles from 47 different Canadian national and regional news sources mentioning the word *suicide* on a daily basis from April 1st 2019 to March 31st 2023 (N=3,232). Each article was read and assessed for adherence to 12 key suicide reporting guidelines using a purposely-built coding sheet, derived from the *Mindset* guidelines. Trends in reporting were analyzed through time series analyses using a GLARMA model in R. software, including measuring for change during the COVID-19 pandemic.
Results: Significant increases in putatively protective content were observed over the four years, including rises in the inclusion of help-seeking information and the quotation of experts. Similarly, there was a general decrease in content that is putatively harmful, for example significantly fewer articles in latter years gave a monocausal explanation of suicide, used sensational language or described in detail any suicide method. That said, fewer than one-third of articles in the final year included educational content about suicide, help-seeking information, or quotes from suicide experts. Reporting of suicide during the COVID-19 pandemic showed some positive improvements compared to pre-pandemic reporting, but these were not sustained post-pandemic.
Conclusions: Fidelity to responsible reporting of suicide guidelines improved over the four-year period, especially recommendations concerning putatively helpful content. However there remains room for improvement regarding inclusion of putatively protective content such as including help-seeking information and educating the public about suicide. As such, further educational outreach to journalists is needed to encourage greater inclusion of protective content, while avoiding harmful content.

ChatGPT and Psychiatric Discharge Summaries: The Assistant We've Been Dreaming of?

J. M. De Castro[1]*, M. Sant'Ovaia[1], C. Martins[1], A. C. Ramos[1] and M. Palma

[1]Serviço de Psiquiatria, Unidade Local de Saúde de Amadora/Sintra, Amadora, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.519

Introduction: ChatGPT is a language model based on artificial intelligence (AI) that is designed to generate human-like text. It offers potential applications in automating and simplification of clinical documentation tasks, addressing the increasing administrative burden that contributes to high rates of burnout in psychiatry. As discharge summaries are typically structured and repetitive, the use of ChatGPT to automate this task could offer significant benefits, such as reducing clinical workload, improving summary quality, and preventing delays in patient discharges. However, concerns about reliability, accuracy, and ethical considerations persist.
Objectives: Explore the feasibility and implications of using ChatGPT to assist in writing discharge summaries in psychiatric settings.
Methods: A narrative review was conducted by searching PubMed and Google Scholar with the keywords "ChatGPT", "discharge" and "psychiatry". Relevant articles, including empirical studies, case reports, reviews, and expert opinions were selected.
Results: We found only one empirical study that evaluated psychiatric discharge summaries generated with ChatGPT-4: human-written discharge summaries were rated significantly higher in quality than those generated by ChatGPT; the ChatGPT summaries fell short, particularly in coherence and specificity of formulations, though they performed reasonably well in summarizing relevant case information. Most of the literature consisted of theoretical discussions and expert opinions related to the broader use of AI in psychiatry. Despite this, the potential benefits, such as improving the efficiency and consistency of documentation, were frequently highlighted. However, concerns related to accuracy, the need for clinician oversight, and ethical implications were consistently noted.
Conclusions: ChatGPT shows promise in assisting with the generation of psychiatric discharge summaries, potentially alleviating the documentation burden faced by clinicians. However, further refinement of the model, integration with electronic health records, and the establishment of clear ethical safeguards are necessary for its safe and effective use. The current lack of empirical evidence highlights the need for targeted research that should also address challenges related to data governance, patient acceptance, and error management. Additionally, studies should evaluate the direct impact on clinician workload and compare the quality of AI-generated summaries with those written by psychiatrists and residents. Such research will be essential to facilitate the broader integration of ChatGPT in real-world psychiatric practice.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.520

Introduction: Public health and policy require effective health strategies for diverse contexts. Despite numerous studies, a gap exists in translating knowledge to real-world scenarios. The RESPOND study's stepped-care intervention has shown efficacy in anxiety and depression among healthcare workers, recognized by the European Commission as a best practice. Conducting a pilot trial in Madrid, we aimed to address this research-to-practice gap.
Objectives: After evaluating a previous randomized controlled trial, we adapted our intervention for a primary care center in Madrid, implementing it over 5-6 weeks in November-December 2023. We used two strategies: remote delivery via app or website with weekly calls, and hybrid, with group sessions instead of calls.
Methods: Gathering data included sociodemographic (age, gender, and type of job), clinical (Kessler Psychological Distress Scale, K-10), and qualitative insights through interviews, to explore implementation outcomes from Proctor's model (Acceptability, Appropriateness, Feasibility, Fidelity, and some ideas for future large-scale implementation). We used mixed methods to analyse data. For the quantative data, we used descriptive statistics such as means, frequencies and percentages to describe the results. For qualitative data, interview transcriptions were analysed following thematic analysis guidelines.
Results: We included 17 out of 39 healthcare workers (44%) working at the primary care center, the sample included 8 doctors, 5 medical residents, 3 nurses, and 1 social worker. Only 3 were male. Over half chose the hybrid option, with 2 dropouts. Regarding clinical information, 88% of participants initially reported psychological distress, but after the intervention, this dropped to 66%. Participants found the intervention timely and appropriate, with an average satisfaction rating of 8 out of 10.
Conclusions: Preliminary findings show the intervention was well-received, and both strategies were successful, reaching a broad audience. Thematic analysis of the interviews is still ongoing. Preliminary results suggest that these strategies are appropriate /feasible for the Madrilenian healthcare system.

doi: 10.1192/j.eurpsy.2025.521

Introduction: Digital wearable devices, such as smartphones and smartwatches, have shown potential for passively monitoring mental and physical health in individuals with Severe Mental Illness (SMI), such as schizophrenia and bipolar disorder. While research-grade devices are well studied, consumer-grade wearables could offer a more accessible alternative, though their utility in this specific context remains underexplored.
Objectives: We conducted a systematic review to assess the utility of data from consumer-grade wearables in tracking and predicting changes in mental and physical health among adults with SMI. We focused on passively collected physiological data, such as sleep patterns, physical activity, and heart rate. We sought to a) identify relationships between data streams and both mental and physical health outcomes and b) recommendations for future digital phenotyping research.
Methods: A systematic review of multiple databases (Cochrane Central Register of Controlled Trials, APA PsycINFO, Embase, MEDLINE, and IEEE XPlore) was conducted in May 2024. Studies that collected passive physiological data for at least three days were included. Narrative methods were used to synthesise results across three key phenotypes: physical activity, sleep and circadian rhythms, and heart rate. Studies using invasive, or research-specific devices were excluded.
Results: In total, 23 studies met the inclusion criteria, representing data from 12 distinct studies and more than 500 participants with SMI, mostly from high-income countries. The majority of studies used smartphones (N=15), with only eight utilizing smartwatches or other wrist-worn wearables. Eighteen studies focused on physical activity, 14 on sleep and/or circadian rhythms, and six on heart rate. We explore the findings of this study, focusing on practical recommendations for future research in the following areas: exploiting opportunities to promote physical health outcomes in SMI; greater standardization of reporting and methodologies; fine tuning longitudinal data collection and feature definition; and comparing alternative data analysis strategies.
Conclusions: Consumer-grade wearables hold significant promise for the passive monitoring of both mental and physical health in individuals with SMI, though current research focuses largely on psychiatric relapse prevention. The findings of this systematic review provide insights into research gaps and future research directions, including tackling physical comorbidities in this population.

doi: 10.1192/j.eurpsy.2025.522

Introduction: Autism spectrum disorder (ASD) is a neurodevelopmental disorder that highly impacts children's development, representing a significant challenge in pediatric healthcare. Parents of children with ASD are nowadays considered as real partners in their children's care. Several parent-mediated interventions (PMIs) have proven to produce sustained improvements in autism symptomatology and social communication. However, widespread access to this type of intervention is still very limited mostly due to geographic and logistic constraints. The use of technology is therefore increasingly considered with the use of videoconferencing and online training modules. In this context, our team developed a novel parental coaching via E-learning (E-coaching) intended for parents of pre-school children with ASD.
Objectives: The ongoing randomized controlled trial aims to evaluate the feasibility and preliminary efficacy of our E-Coaching program compared to a standard coaching and a control group with no PMI.
Methods: The present study is a monocentric randomized controlled trial with three arms (E-coaching, Standard coaching, Control) of 33 children (N=99). Feasibility was assessed across recruitment, acceptability and implementation using semi-structured interviews. The primary outcome will be the quality of parent-child interaction, measured using a range of behavioral observations and by monitoring parent and child gaze using two head-mounted eye-tracking systems during semi-structured standardized play sessions. Secondary outcomes will include child's developmental level through neuropsychological testing, and parental wellbeing through several standardized parent-report questionnaires.
Results: We present preliminary evidence supporting the feasibility and acceptability of the intervention, with participants reporting positive benefits on parent-child interaction. Preliminary observational data on the first families provided support for an improvement on parent-child interaction immediately after the end of the E-coaching intervention, as well as an increase of parental wellbeing.
Conclusions: We found initial feasibility for our E-coaching program, suggesting that parent-mediated E-learning interventions may be a promising format to implement with ASD families. Further evaluation to assess efficacy of the intervention is warranted and underway. If validated, E-coaching will enable us to reach a larger number of families and to have an early and meaningful impact on the developmental trajectory of these children, and on their quality of life.

doi: 10.1192/j.eurpsy.2025.523

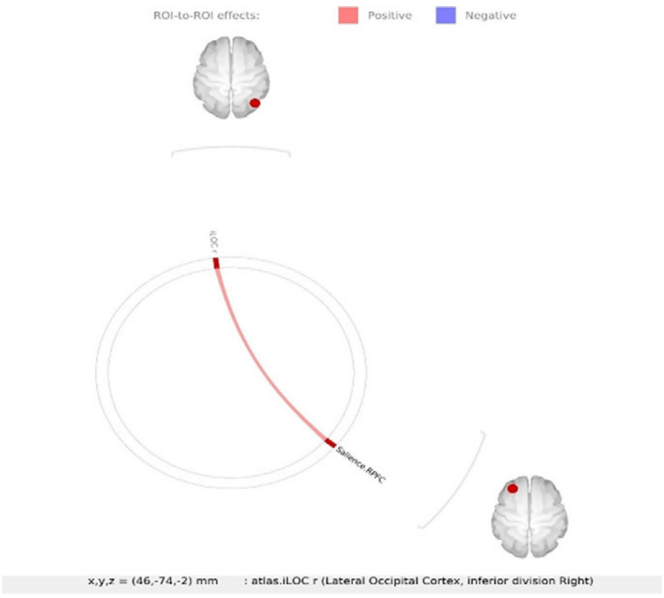
Introduction: Previous resting-state fMRI studies have found hypoconnectivity between the areas underlying default mode and salience networks in OCD patients. A general dysconnectivity has been observed between the frontoparietal network and corticostriatal-thalamocortical loops in patients with OCD, We conducted a study to understand the neural correlates of OCD and its sub-types and compared them with healthy controls. As a part of the analysis of fMRI data, we also analyzed the resting state data for OCD patients and compared it to that of healthy controls.
Objectives: To study the neural correlates of OCD using functional MRI by comparing the resting state functional connectivity in OCD patients with healthy controls.
Methods: We used the resting state functional MRI data of 8 OCD patients and compared it with 10 healthy controls. The healthy controls and patients were not age—and sex-matched. The resting state fMRI data was assessed using the CONN functional connectivity toolbox, version 15.d, in MATLAB. The Regions of interest (ROIs) were mapped using the MNI coordinate system. The functional connectivity (FC) was studied with ROI-to-ROI analysis and seed-to-voxel analysis.
Results: 1. In ROI to ROI analysis between resting state networks, only one significant result was found when FC between all the brain networks was compared. as shown in table 1 and image 1.

Table 1.

Seed	Target	T-statistic	X, Y, Z	p-uncorrected	p-FDR corrected
Lateral Occipital Cortex, inferior division Right (iLOCr)	Salience rostral pre-frontal cortex	T(16) = 5.32	46, -74, -2	0.0001	0.0112

2. Seed-to-voxel-based analysis revealed that at p-FWE <0.05 corrected, the left and right occipital pole and right intra-calcarine cortex were more active in OCD patients as shown in image 2.

Image 1:



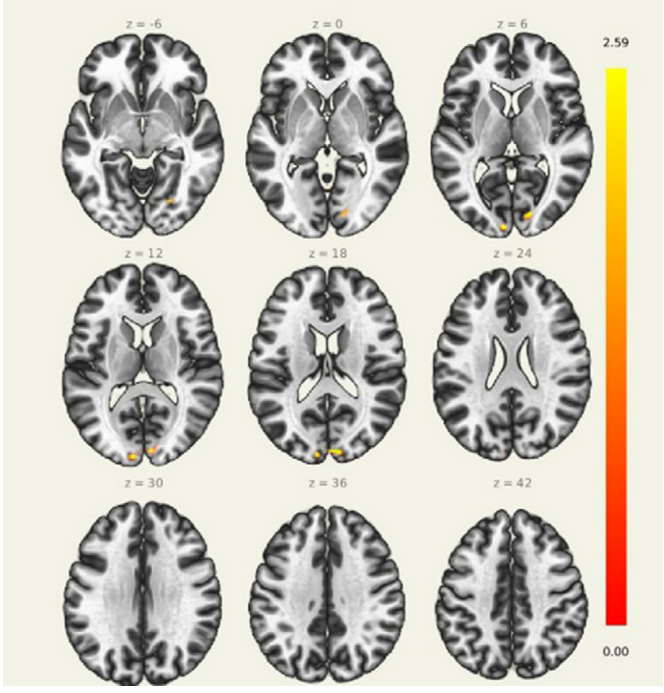


Image 2:

Conclusions: 1. ROI TO ROI analysis: Attempts to gain control over automatic processes are taxing on the cognitive resources and effective control is lacking in OCD, which could explain higher functional connectivity in the areas linked to having selective attention for specific visual stimuli as found in our study. The lateral occipital cortex supports both visual perception and multisensory integration and visual cortices have been seen to contribute to impulsivity and disorders commonly associated with impulsivity. The rostral prefrontal area in the salience network is involved in sequence selection and evaluation and has a possible role in attention. DMN and corticostriatal networks were normal possibly due to the small sample size, patients on treatment, etc.
2. Seed to Voxel Analysis showed left as well as right occipital poles and right intra-calcarine cortex which process visual stimuli, were more active at rest in OCD patients. Some studies have highlighted deficits in visuospatial processing in OCD patients. The intra-calcarine cortex would require further research for a better understanding of its role in OCD patients.

Beyond Cartesian Dualism: Neuropsychiatric Presentation of Fahr's Syndrome Secondary to Pseudohypoparathyroidism: A Case Report

M. Fatima[1]*, A. Aslam[2], F. A. Randhawa[3], Z. Khalid[4], S. Mumtaz[4], M. S. Alam[4] and A. Nawaz[2]

[1]Psychiatry, Dublin North Mental Health Service, Dublin, Ireland; [2]Neurology; [3]Endocrinology/ General Medicine and [4]King Edward Medical University , Lahore, Pakistan
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.524

Introduction: Fahr's Syndrome is a rare disorder characterized by abnormal brain calcium deposits presenting as extrapyramidal signs, cognitive impairment, movement disorders, and psychiatric symptoms. Though well documented in association with hypoparathyroidism, its presentation secondary to pseudohypoparathyroidism (PHP) is exceptionally unusual.
Objectives: To report a rare neuropsychiatric presentation of Fahr's Syndrome secondary to PHP.
Methods: We report this rare case following the CARE Case Report guidelines.
A 25-year-old female was admitted to the neurology ward after a referral from the Psychiatry clinic for dysarthria, involuntary movements affecting gait and daily activities, worsening psychomotor slowing for five years & depressive symptoms for around a year. She had difficulty controlling anger for 2.5 years & 2 impulsive attempts at self-harm in the past 6 months with no suicidal intent in which she tried to slash her wrist & jump off the rooftop over verbal confrontations with family (Image1).
Results: Neuroimaging revealed bilateral, symmetrical calcifications in basal ganglia, thalami, red nuclei, the gray matter of bilateral occipital and frontal lobes, and cerebellar hemispheres (Image 2). Image 3 shows MRI Brain (with contrast) axial section images: Altered hyperintense signals in bilateral basal ganglia & red nuclei of midbrain on T1WI, hypointense signals on T2/FLAIR, and Blooming artifacts on SWAN images.
She was diagnosed with PHP based on hypocalcemia, hyperphosphatemia, high intact parathormone (PTH), and normal Serum Vitamin D levels. The absence of Albright's Hereditary Osteodystrophy (AHO) phenotype and normal thyroid profile suggested PHP-type 2/1B but we couldn't perform the Ellsworth Howard test to distinguish due to the unavailability of synthetic PTH. She was

treated with oral calcium supplements, oral active vitamin D (CALCITRIOL or 1, 25-DIHYDROXYCHOLECALCIFEROL), CALCIUM ACETATE, AMANTADINE, ALFACALCIDOL, and ESCITALOPRAM leading to significant improvement in depressive symptoms, and normocalcemia at one-year follow-up.

Image 1:

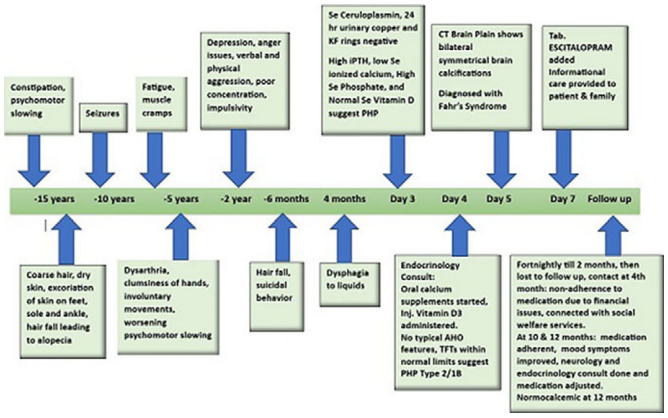

Image 2:

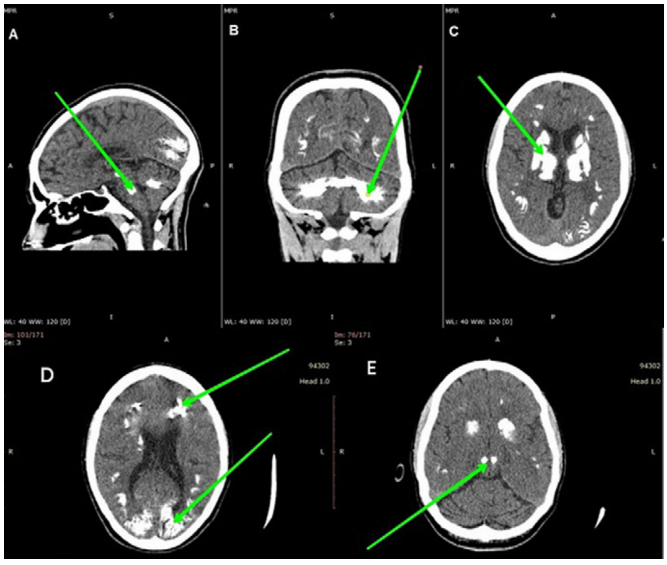

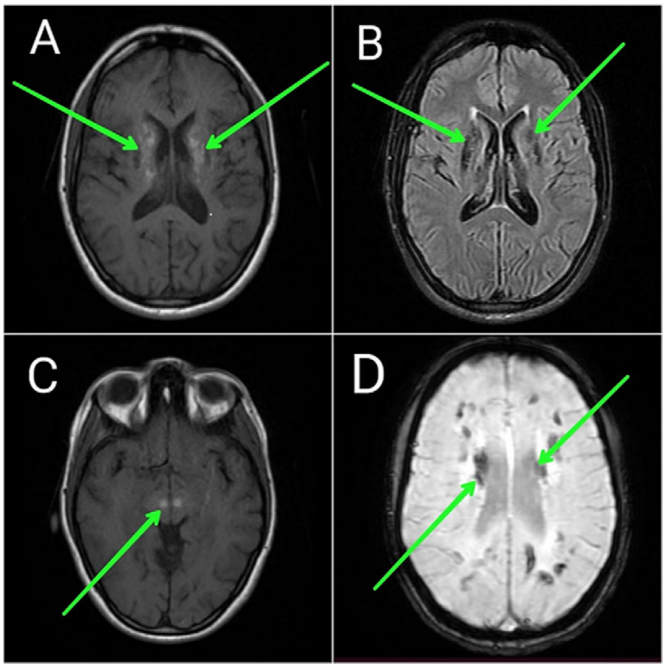

Image 3:

Conclusions: The diagnosis and management of rare neuropsychiatric syndromes maybe challenging in low-resource settings and timely diagnosis and management necessitate looking beyond the mind-body dualism and ensuring a multidisciplinary approach. Our patient's neurological features were overlooked at a specialist mental healthcare facility for 5 years which accentuates the significance of thorough neurological assessment during psychiatric evaluations and of incorporating neuropsychiatry and psycho-neuro-endocrinology into the training and practice of psychiatry and neurology in Pakistan. This case also provides insights into the economic barriers to the management of neuropsychiatric disorders in a lower middle-income country (LMIC), where high out-of-pocket expenditure on treatment may result in loss of follow-up.

doi: 10.1192/j.eurpsy.2025.525

Introduction: Schizophrenia (SCZ) is a mental disorder with as yet undefined aetiology and pathogenesis. It is currently considered as a neurodevelopmental disorder and one of the main causes of disability globally, with a prevalence of approximately 1%. About one in four individuals with SCZ is diagnosed with comorbid Cannabis Use Disorder (CUD). Aberrations in brain connectivity have been identified as contributing to the pathophysiology of SCZ.
Objectives: To our knowledge, no resting-state functional magnetic resonance imaging (rs-fMRI) study has compared continued cannabis use in SCZ patients with CUD (SCZ-CUD$^+$) *vs.* patients with SCZ without cannabis use (SCZ-CUD$^-$). We hypothesised that continued cannabis use, could result in greater impairment of clinical and cognitive symptoms and in altered connectivity in the Salience Network (SaN), in striate/extended amygdala-cortical areas, and in those involved in planning and emotional control. Studying connectivity in patients with SCZ and CUD could elucidate the mechanisms underlying the development of psychotic symptoms and vulnerability to substance use relapse.
Methods: We included 14 SCZ-CUD$^+$ and 20 SCZ-CUD$^-$ patients. All were assessed cross-sectionally through the Neurological Evaluation Scale, the Brief Assessment of Cognition in Schizophrenia, the Positive And Negative Syndrome Scale and the Clinical Global Impressions Scale-Severity, and underwent brain rs-fMRI with a 1.5 T scanner to explore functional connectivity (FC). *Imaging protocol:* All patients underwent a brain 1.5 T MRI scan (GE Signa Voyager) with 32-channel phased-array head coil. Beside the conventional morphological sequences, the functional MRI protocol included: 1) rs-fMRI obtained with a gradient-echo echo-planar imaging (EPI) sequence. Each scan session lasted for 6 min. 2) Structural imaging involved a sagittal three-dimensional sequence employing a magnetisation prepared rapid gradient echo (MPRAGE) over the whole brain.
Results: CUD in SCZ patients was associated with higher impulsiveness and excitement, and lower negative symptoms and neurological soft signs (Fig.1). SCZ-CUD$^+$ and SCZ-CUD$^-$ groups differed little on cognitive performance, except for Symbol Coding, where SCZ-CUD$^-$ outperformed SCZ-CUD$^+$. Rs-fMRI, compared to SCZ-CUD$^-$, showed reduced FC in patients with SCZ-CUD$^+$ between regions of the salience network, including anterior cingulate and prefrontal cortices, and between right insula and dorsolateral prefrontal cortex and precuneus (Fig.2, Fig.3).

Image 1:

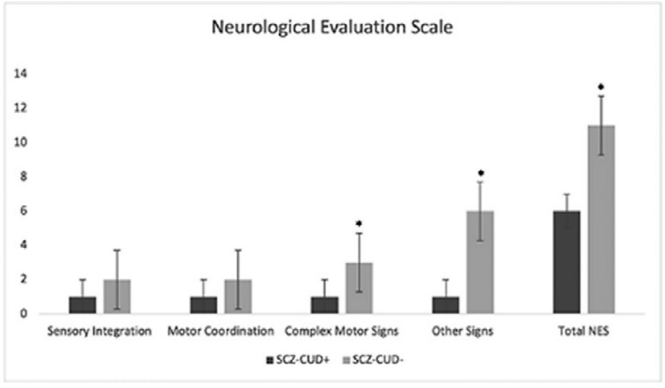

Image 2:

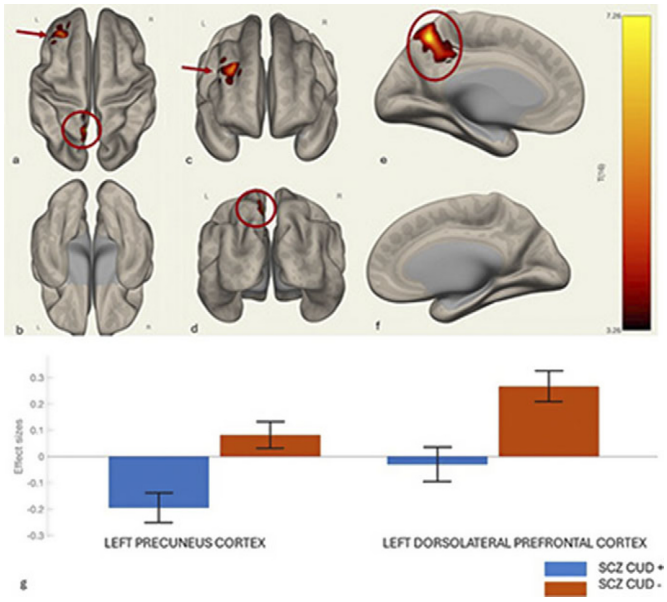

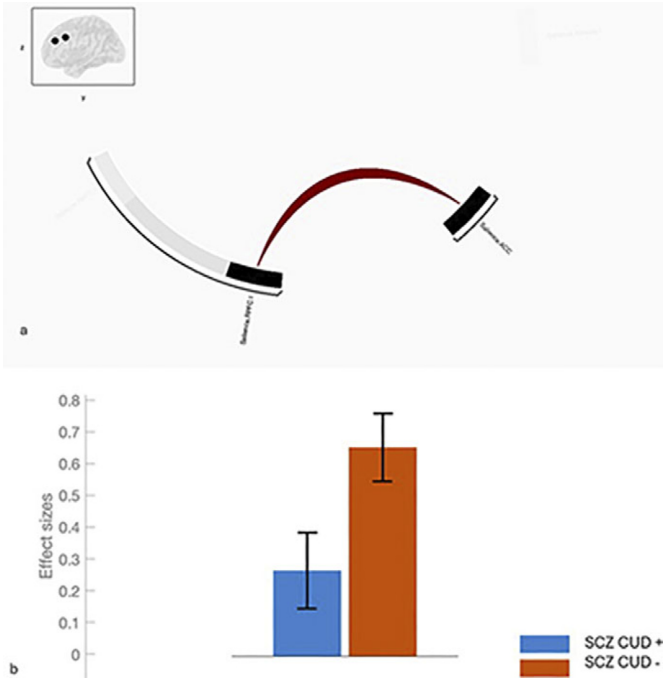

Image 3:

Conclusions: Using rs-fMRI, we revealed differences in FC within the SaN between SCZ-CUD$^-$ and SCZ-CUD$^+$. Continuous cannabis use reduces FC in cortical circuits, impacting connections already impaired in SCZ. In SCZ-CUD$^+$ patients, altered self-relevance attribution and insular dysfunction may increase drug-related impulses and impair cognitive control.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.526

Introduction: Despite extensive investigation, the neurophysiological underpinnings of ASD remain poorly understood; a predominant hypothesis relates to the activity of the brain's mu-rhythm (defined as the frequency band ranging between 8–14 Hz topographically centered over the sensorimotor cortex) and the so-called "Mirror Neuron System" (MNS), considered as an execution-imagination-observation matching system. In particular, mirror neurons (MN) are bimodal neurons located in the ventral premotor cortex, discharging both when a goal-directed action is performed and when it is observed. Previous studies investigating mu-wave suppression in individuals with ASD were limited by having consistently employed video clips filmed with a fixed camera position, hence not including the potential movement of the observer towards the other person (a condition perceived as more ecological and close to reality).
Objectives: Aim of this study was to investigate differences in mu-wave modulation in individuals with Autism Spectrum Disorder (ASD) without intellectual disabilities with respect to a group of neurotypical controls (NT).
Methods: Thirty individuals with ASD and thirty NT underwent an EEG recording while watching short videos depicting goal-oriented action filmed from a fixed position, zooming in on the scene, and approaching the scene by means of a steadycam. Afterwards, participants underwent a rating task to evaluate their subjective viewing experience.
Results: Steadycam videos elicited enhanced event-related desynchronization (ERD), suggestive of an enhanced neural activity, in the NT group, and a reduced ERD in the ASD group, with respect to the other filming conditions. ASD participants also showed difficulties in returning to baseline mu-power levels after watching videos filmed from a fixed position. NT reported to feel more comfortable watching videos with movement, whereas participants with ASD did not exhibit differences between conditions.
Conclusions: The ecological nature of video recording (i.e., visual stimuli filmed with a steadycam) seems to have an opposite effect on the ASD an NT population, as it enhances mu-wave suppression in NT, and reduces it in individuals with ASD, bringing them to a level of desynchronization closer to the one of NT. Understanding these differences might help developing tailored interventions to support perceptual, cognitive, and social processes of people with ASD.

Varying Impacts of MRI-Detected Lesions on Cognitive Function in CADASIL Patients

J. H. Park[1,2]*, H. J. Yang[1,2] and S. H. Lee[2]

[1]Psychiatry, Jeju National University Hospital and [2]Psychiatry, Jeju National University, Jeju, Korea, Republic Of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.527

Introduction: Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy (CADASIL) is a hereditary cerebrovascular disorder caused by point mutations in the NOTCH3 gene located on chromosome 19. The condition is primarily characterized by three core MRI lesions: white matter hyperintensities (WMH), lacunar infarcts, and cerebral microbleeds. Unlike age-related MRI lesions, which can be attributed to multiple factors such as aging, hypertension, and diabetes, the lesions in CADASIL are linked to a single genetic cause, offering a more uniform model for studying the impact of lesion location.
Objectives: This study focuses on CADASIL patients and aims to identify factors associated with dementia while examining the relationships between total WMH volume, WMH location, lacunar infarct count, cerebral microbleeds, and cognitive performance.
Methods: A total of 81 participants were included in the study. Each participant underwent both brain MRI and the CERAD neuropsychological battery. White matter hyperintensity (WMH) volume was assessed via MRI, and the WMHs were categorized by their proximity to the ventricular surface into three types: juxtaventricular (JVWMH), periventricular (PVWMH), and deep white matter hyperintensities (DWMH). DWMH included lesions located beyond 13 mm from the ventricular surface. Additionally, MRI was used to evaluate the number of lacunar infarcts and cerebral microbleeds (CMB) present.
Results: The prevalence of dementia among CADASIL patients was 18.5%. Logistic regression analysis revealed an odds ratio of 1.078 (95% CI = 1.011–1.150) for WMH volume. Similarly, However, the number of lacunar infarcts and CMB did not demonstrate a significant relationship with dementia risk. Linear regression analysis indicated that total WMH volume was significantly linked to performance on several cognitive tests. When WMH volume was categorized by distance from the ventricular surface, JVWMH volume and PVWMH volume werr significantly associated with performance on various cognitve tests. Conversely, DWMH volume did not demonstrate a significant association with cognitive performance in CADASIL patients. The number of lacunar infarcts was correlated with performance on the trail-making test A, the Stroop word test, and the Stroop color test, while cerebral microbleeds did not show significant associations with cognitive performance.
Conclusions: Core MRI-detected lesions exhibit diverse impacts on cognitive function in CADASIL patients. Total WMH volume and JVWMH volume showed a significant correlation with dementia diagnosis. However, DWMH volume did not demonstrate a significant relationship with either dementia diagnosis or specific cognitive functions. The number of lacunar infarcts was notably associated with visual search speed, while CMB were not significantly connected to dementia diagnosis or any particular cognitive functions

EPP209

Differentiation between suicide attempt and suicidal ideation in patients with major depressive disorder using cortical functional network

S. Shim

psychiatry, soonchunhyang university cheonan hospital, cheonan, Korea, Republic Of

doi: 10.1192/j.eurpsy.2025.528

Introduction: The detection of electrophysiological markers to differentiate patients with suicide attempts could support the efforts of clinicians to provide proper diagnosis and treatment for them, and finally reduce the suicide mortality rate.

Objectives: The objective of the current study was to investigate and compare cortical functional networks from resting-state electroencephalogram in patients with suicide attempts and suicidal ideation using source-level weighted network analysis. We also examined the possibility of network features serving as biomarkers by differentiation between suicide attempts and suicidal ideation using machine learning techniques.

Methods: This study investigated source-level cortical functional networks using resting-state electroencephalography in drug-naïve depressed patients with suicide attempt and suicidal ideation. Electroencephalogram was recorded in 55 patients with suicide attempts and in 54 patients with suicidal ideation. Graph-theory-based source-level weighted functional networks were assessed using strength, clustering coefficient (CC), and path length (PL) in seven frequency bands. Finally, we applied machine learning to differentiate between the two groups using source-level network features.

Results: There were significant differences in the three global level indices of the high alpha band. The strength and CC of the high alpha band were significantly lower in patients with suicide attempts than in those with suicide attempts ideation. In contrast, the PL of the high alpha band was significantly higher in patients with suicide attempts than in those with suicide ideation. No significant differences in the other frequency bands were between the two groups.

The nodal CCs of patients with suicide attempts were significantly lower than those of patients with suicide ideation in most regions, except for three of the 68 regions.

The best classification performance between suicide attempts and suicide ideation was an accuracy of 73.39%, a sensitivity of 76.36%, and a specificity of 70.37% with 17 features. Three of these features were global-level network indices (strength, CC, and PL) in the high alpha band; the other 14 features were high alpha band nodal level CCs in limbic, frontal, temporal, parietal,and occipital area.

Image 1:

Table 2
Mean and standard deviation values of global network indices including strength, clustering coefficient (CC), and path length (PL) in each frequency band in suicide attempt and suicide ideation groups.

	Suicide attempt (N = 55)	Suicide ideation (N = 54)	Effect size (η^2)	p^*

* The *p*-value was adjusted via Bonferroni correction with 0.05/68 = 0.000735.

Image 3:

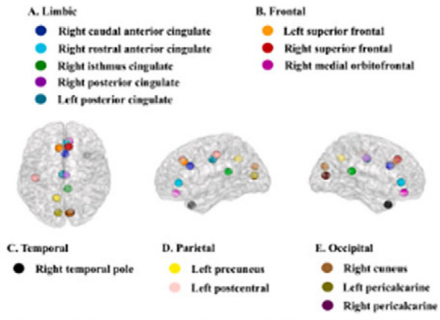

Fig. 1. Brain regions of high alpha band nodal clustering coefficients showing the best classification performances between suicide attempt and suicide ideation groups.

Conclusions: This is the first study to use electroencephalogram source level network measures, revealing that network indices for high alpha band could be potential biomarkers to distinguish betweensuicide attempts and suicide ideation in patients with depression. Moreover, our study evaluated the electroencephalogram signals immediately after fatal suicide attempts in a relatively large number of un-medicated patients.

doi: 10.1192/j.eurpsy.2025.529

Introduction: Attention-deficit/hyperactivity disorder (ADHD) is one of the most prevalent mental disorders diagnosed in children and is characterized by complex, interacting symptoms. Although executive functioning systems are most frequently examined in functional magnetic resonance imaging (fMRI) activation studies of ADHD, atypical reward processing may also play a central role in ADHD and influence other symptoms, such as hyperactivity and impulsivity. This meta-analysis aims to advance our understanding of the neural basis of reward processing in ADHD, as measured by fMRI activation studies.
Objectives: The present study aims to advance our understanding of the neural basis in reward processing in participants with ADHD by identifying aberrant functional activation in various brain regions compared with healthy controls.
Methods: We conducted a comprehensive literature search in PubMed for whole-brain, task-based fMRI activation studies comparing participants diagnosed with ADHD to healthy controls in accordance with PRISMA guidelines. We then used multilevel kernel density analysis (MKDA) with ensemble thresholding (α = .05–.0001; FWE-corrected) to explore neural activation patterns associated with ADHD across all tasks and during reward processing tasks.
Results: We obtained 57 primary studies (N = 4,366) that met our inclusion criteria. We found that patients with ADHD (n = 1,591), relative to healthy controls (n = 2,775), exhibited statistically significant (p < .005; FWE-corrected) differential activation in multiple brain regions of the cerebral cortex and basal ganglia, including robust effects across various tasks and task-specific effects observed during reward processing.
Conclusions: These findings strengthen our understanding of the neural basis of reward processing in ADHD, which may inform new neurocognitive models of this heterogeneous disorder. Future studies should investigate disorder-specific and transdiagnostic neural features of ADHD and reward processing and explore clinical applications such as non-invasive brain stimulation and neurofeedback training.

Structural and dynamic vascular factors are not related to apathy over time: time to rethink the vascular apathy hypothesis?

A. S. Bertens[1,2*], K. Moret[1,3], J. Van der Grond[4], R. Poortvliet[5] and N. Rius Ottenheim[1]

[1]Psychiatry, Leiden University Medical Center; [2]Old Age Psychiatry, Rivierduinen GGZ Mental Health Services; [3]Faculty of Social Sciences, Leiden University; [4]Radiology and [5]Public Health and primary care, Leiden University Medical Center, Leiden, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.530

Introduction: Apathy frequently occurs in older persons but its aetiology is not understood as of yet. One hypothesis, the vascular hypothesis of apathy, suggests a link between apathy and vascular factors such as cerebral small vessel disease (CSVD), that may cause lesions in the reward network of the brain. In previous studies, a cross sectional association was found between lower blood pressure (BP) and symptoms of apathy in older persons with more CSVD, potentially through reduced cerebral blood flow (CBF). However, longitudinal studies on associations between vascular factors and apathy are scarce.
Objectives: We investigated whether in older persons, structural and dynamic vascular factors are associated with apathy symptoms over time. We hypothesized that a higher burden of CSVD, a lower BP and lower CBF, would be related to an increase in symptoms of apathy.
Methods: This study is a longitudinal cohort study involving community-dwelling older participants of the Discontinuation of Antihypertensive Treatment in the Elderly (DANTE) Study, all using antihypertensive treatment and with mild cognitive deficits. At baseline BP was measured and apathy was assessed with the Apathy Scale (AS, range 0-42) at baseline and after four years of follow-up (n=178). Additionally, a baseline MRI sub study (n=109) was conducted to measure CSVD and CBF. Univariate and multivariate linear regression analyses were performed using CSVD, BP and CBF as determinants and the change in Apathy Scale score over time as an outcome.
Results: Mean age of the population was 80 years (SD 4) and 63% was female. In the MRI sub study, no significant association was found between the summary CSVD scores (β (95% CI)=0.018 (-1.089-1.125), p=.975) or it's separate features; WMH (β(95% CI)=0.012(-0.011-0.035), p=.318), CMB (β (95% CI)=-0.017 (-0.605-0.572), p=.956), lacunar infarctions (β(95% CI)=-0.413 (-1.266-0.440), p=.339), and a change in Apathy Scale score. Additionally, no significant association between the dynamic vascular factors; CBF (β(95% CI)=-0.029(-0.152-0.094), p=.640), systolic BP (β (95% CI)=-0.019 (-0.056-0.018), p=.310) and diastolic BP (β(95% CI)=-0.029(-0.099-0.042), p=.425), and change in Apathy Scale score was found. The multivariate linear regression model, which incorporated all the structural and dynamic vascular parameters, age, and gender, was not significant.
Conclusions: In older persons with mild cognitive deficits, structural and dynamic vascular factors were not associated with symptoms of apathy after four years of follow-up. Our findings thus do not support a 'vascular apathy hypothesis'. Potentially, other factors such as life style factors confound the cross sectional association between vascular factors and apathy, or different apathy syndromes may have different aetiologies. Larger studies with less baseline vascular burden, are needed to confirm our results.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.531

Introduction: Late-life depression (LLD) has been linked to increased likelihood of dementia, although mechanisms responsible for this association remain largely unknown. One feature frequently observed in both LLD and dementia is elevated levels of plasma inflammatory markers.
Objectives: The present study aimed to compare the levels of 12 plasma inflammatory markers between older people with LLD and controls, and to explore whether these markers, along with clinical characteristics, can predict dementia in patients with LLD within 3 years of follow-up.
Methods: Using multiple linear regression with stepwise adjustment (for age, gender, smoking status, and physical comorbidities), we compared levels of plasma inflammatory markers (IL-1β, IL-1ra, IL-6, IL-10, IL-17a, IL-18, IL-33, TNFα, CD40L, IFN-γ, CCL-2 and CCL-4) between 136 older inpatients admitted to psychiatric units for LLD (PRODE cohort) and 103 cognitively healthy non-depressed controls (COGNORM cohort). In the PRODE cohort, follow-up data was available for 139 patients (of them 123 had data on baseline plasma inflammatory markers); 36 (25.9%) developed dementia by year 3. Using Cox proportional hazards regression, we explored whether inflammatory markers and clinical characteristics of LLD (age of onset, treatment response, number of episodes) predicted progression to dementia during follow-up.
Results: Levels of IL-1ra, CCL-2, CCL-4, IFN-γ and IL-17a were significantly higher in LLD patients compared to controls in all models (See Fig 1); IL-33 was significantly elevated in most models. None of the baseline plasma inflammatory markers predicted progression from LLD to dementia. Among clinical features, only improvement in MADRS score at discharge (HR = 0.95, 95% CI 0.91-0.99) and treatment response (HR 0.45, 95%CI 0.21 – 0.98) were associated with lower chance of progression to dementia in

fully adjusted models; age of onset and number of previous episodes were not significant predictors of dementia at follow-up.

Image 1:

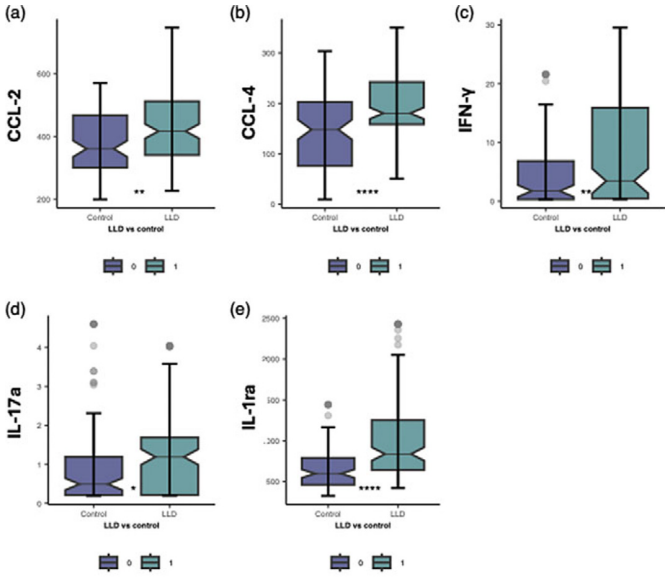

Fig.1 Boxplots illustrating differences in concentrations of 5 plasma inflammatory markers between participants with LLD (n=136) and controls (n=103): (a)CCL-2; (b) CCL-4; (c) IFN-γ; (d) IL-17a; (e) IL-1ra. These 5 inflammatory markers emerged as significantly higher in LLD compared to control group after full adjustment for covariates.
***p<0.001; **p<0.001; *p<0.05

Conclusions: This study demonstrated an increase in plasma inflammatory markers in LLD but did not find evidence they could predict dementia at follow-up.

EPP215

Anxiety and depression among patients with age-related macular degeneration

S. V. Kuzmina[1]* and D. A. Yakovlev[1]

[1]Psychiatry and medical psychology, Kazan State Medical University, Kazan, Russian Federation
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.532

Introduction: AMD is currently the main cause of deterioration in the quality of life, disability and blindness in people over the age of 50 in economically developed countries,the presence of symptoms of anxiety and/or depression may be a risk factor for the development and exacerbation of ophthalmological diseases, a risk factor for an unfavorable prognosis of the disease and one of the factors contributing to a decrease in the patient's compliance and motivation for ophthalmological treatment
Objectives: The aim was to study the prevalence of symptoms of anxiety and depression in patients with age–related macular degeneration and determine its impact on quality of life.
Methods: A continuous sampling method was used to examine 24 patients (9 men and 15 women, aged from 41 to 87 years, the average age in the group was 69.7 ± 10.8 years) with an established diagnosis of AMD, who were undergoing inpatient treatment at the Cheboksary branch of the FSAU NMIC MNTC Eye Microsurgery. Academician S.N. Fedorova" Ministry of Health of Russia, HADS, The Spielberger anxiety Questionnaire, SF-36,The results of the examination of the mental state were compared with the indicators of visual acuity
Results: Clinically significant severity of depression symptoms was found in 4.2% of patients, mild manifestations of depression were found in 8.3%, 79.2% demonstrated moderate reactive anxiety; 12.5% of the subjects had a low level of reactive anxiety. 81.7 % of the respondents were subject to moderate and high personal anxiety. men were more prone to manifestations of both reactive (88.9% of men and 73.3% of women, respectively) and personal anxiety (100% of men and 86.7% of women, respectively), higher incidence of depression among women than among men. Patients with lower visual acuity tended to give a lower assessment of their physical health.
Conclusions: The results demonstrated a high prevalence of personality and reactive anxiety among patients with age-related macular degeneration. At the same time, persons with higher acuity vision was more prone to anxiety, which may probably be due to incomplete adaptation to pathology in the early stages of AMD development. A tendency was found to have a worse assessment of their physical well-being among older patients with lower visual acuity.
This study has a limitation due to the small sample of patients at the time of analysis, which dictates the need for further study of this issue.

Mind Games: When Neurosyphilis and Borderline Personality Disorder Collide – A Diagnostic Puzzle

A. G. Buciuc[1]*, A. D. Gurfinchel Zevallos[1] and M. Hadjikyriakou[2]

[1]Psychiatry, University of Miami/ Jackson Health System and [2]Psychiatry and Behavioral Sciences, Bruce W. Carter Department of Veterans Affairs Medical Center, Miami, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.533

Introduction: Historically, syphilis has been known as "the Great Imitator" due to its heterogeneous clinical manifestations. Though its incidence decreased with the widespread use of penicillin, recent data suggest a resurgence, particularly among those experiencing delays in treatment. This resurgence creates diagnostic challenges, especially when patients have coexisting psychiatric conditions like Borderline Personality Disorder (BPD).
Objectives: This report explores the psychiatric and cognitive manifestations of neurosyphilis in patients with preexisting personality disorders. The primary objective is to highlight how neurosyphilis complicates psychiatric diagnosis and care and to emphasize the need for early detection and intervention.
Methods: A thorough literature review was conducted using PubMed database covering studies published from 2000 to 2023. Keywords included "neurosyphilis," "borderline personality disorder," "psychiatric symptoms," "syphilis resurgence," and "cognitive impairment."

Additionally, the case of a 35-year-old female with BPD who developed neurosyphilis is presented, demonstrating the complexities in distinguishing between overlapping psychiatric symptoms. The case also emphasizes the importance of comprehensive care.
Results: The psychiatric symptoms of neurosyphilis, such as impulsivity, mood instability, and cognitive dysfunction, significantly overlap with those of BPD, complicating diagnosis and treatment. Literature indicates that neurosyphilis occurs in 0.5% to 2% of untreated syphilis cases. Common psychiatric manifestations of neurosyphilis—such as irritability, cognitive decline, and affective dysregulation—are often misattributed to underlying psychiatric disorders, leading to delays in proper treatment. In the case of the 35-year-old patient, her longstanding BPD symptoms, including emotional instability and impulsivity, worsened with the progression of neurosyphilis. Cognitive testing revealed mild impairment, which was consistent with the cognitive decline seen in neurosyphilis, further complicating the clinical picture.
Conclusions: This case underscores the critical need for timely syphilis screening, particularly for individuals with a history of untreated or inadequately treated infections. Early diagnosis and treatment of neurosyphilis can significantly improve cognitive and psychiatric outcomes while promoting overall wellness. Routine sexually transmitted disease screenings, especially in psychiatric populations, can prevent severe neuropsychiatric complications and support holistic well-being. Given the global resurgence of syphilis, a proactive approach to sexual health is essential in fostering both mental and physical health.

Neuropsychiatric Symptoms in Huntington's Disease: A Case Report on Manic and Psychotic Features Huntington's disease (HD)

S. Buyo Lagares[1]*, A. Picallo Vieito[1], M. Grueiro Cao[1], M. Pardal Iglesias[1], A. Lagoa Pena[1], C. Ramil López[1], C. Ovies Fernández[1], A. Parada Barcia[1], P. Piñeiro Magro[1], L. González Pereira[1], J. Ricoy Chaín[1] and R. Prieto Pérez[1]

[1]Hospital A Coruña, A Coruña, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.534

Introduction: Huntington's disease (HD) is a hereditary neurodegenerative disorder marked by progressive declines in motor, cognitive, and psychiatric functions. This case report presents a 45-year-old female patient with HD who displayed significant manic symptoms, which later evolved into acute psychosis. Notably, her neuropsychiatric symptoms emerged months before motor deficits. This case aims to raise clinician awareness of the interplay between neuropsychiatric symptoms and HD.
Objectives: Analyze early neuropsychiatric manifestations, particularly manic and psychotic symptoms; highlight the importance of recognizing these symptoms before the onset of motor dysfunction; and explore the neurobiological mechanisms underlying, including neurotransmitter dysregulation and structural brain changes.
Methods: A comprehensive clinical evaluation was conducted for the patient. Her psychiatric history was assessed using standardized tools, including the Young Mania Rating Scale (YMRS) and the Positive and Negative Syndrome Scale (PANSS). Neuroimaging, including computed tomography (CT), assessed structural brain changes in regions related to mood regulation and psychosis, such as the striatum and prefrontal cortex. A literature review correlated these findings with existing research on neurobiological mechanisms in HD, focusing on neurotransmitter systems and brain morphology.
Results: Initially, the patient exhibited manic symptoms such as elevated mood and irritability, with moderate severity noted on the YMRS. Within a month, her condition escalated to acute psychosis, featuring auditory hallucinations and paranoid delusions, as reflected by moderate PANSS scores. Neuroimaging revealed structural changes consistent with HD, including striatal atrophy and prefrontal cortex alterations. These findings supported the hypothesis of neurotransmitter dysregulation, particularly involving dopamine and serotonin.
The management plan included mood stabilizers and antipsychotics, such as valproic acid and risperidone, along with temporary benzodiazepines to manage agitation. This approach led to a significant reduction in both manic and psychotic symptoms, improving the patient's overall quality of life through integrated psychiatric care.
Conclusions: This case underscores the importance of recognizing early neuropsychiatric symptoms, particularly manic and psychotic features, in HD patients. The emergence of these symptoms prior to motor dysfunction calls for heightened clinician awareness, as early identification can facilitate timely interventions and enhance patient outcomes. The observed structural brain changes and neurotransmitter dysregulation suggest underlying neurobiological mechanisms, warranting further research in the broader HD population. A multidisciplinary approach is essential for effectively managing the interplay of neuropsychiatric symptoms.

Test-Retest Reliability and Informant Consensus Pilot Study of the BRIEF-A in the Non-Clinical Spanish Population

I. González Herrera[1]*, R. Sandoval Rodríguez[2], A. B. Calvo Calvo[1] and J. M. Espejo-Saavedra Roca[1,3]

[1]Personality, Assessment and Clinical Psychology Department; [2]Universidad Complutense de Madrid and [3]Hospital Universitario 12 de Octubre, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.535

Introduction: Executive functions (EEFF) are different cognitive aspects that allow us to find solutions and adapt to changes. There are several traditional instruments that assess these processes, but they are difficult to generalize to the subject's real environment.
Objectives: To analyze the test-retest reliability of the adaptation of the BRIEF-A to the Spanish population with a non-clinical sample, as well as studying the informant consensus between the Self-report and Informant report forms that this instrument presents.
Methods: The questionnaire has been administered to 58 subjects from the general population (Self-report version) and 58 informants who adequately knew each subject (Informant report version) at baseline and at 4 weeks follow-up in order to study the test-retest reliability. Statistical analysis was carried out using the Pearson Correlation Coefficient to study the test-retest reliability. Self-reports

and Informant reports mean scores were also compared using the Student's T-Test for paired samples.
Results: The calculated correlations were significant for all the scales and indices in both the Self-report and the Informant report versions, and relatively strong in all the cases with values ranging from 0.62 to 0.89 except for the Task Monitor scale in the Self-report form, which presented a moderate correlation (r = 0.31). When it comes to the T-Test, mean differences between the two samples were also statistically significant in all the cases.
Conclusions: Test-retest reliability of the BRIEF-A is adequate in the non-clinical Spanish population, and the scores obtained in the first occasion remain relatively stable in the second. Furthermore, the informant consensus is observed to be low, therefore showing the utility of gathering data from different informants, since that can provide a better approach of subjects EEFF. Further research with clinical population would be necessary to validate this tool and perform a complete assessment.

Perceived hope affects mental health among Portuguese Adults in year three of the COVID-19 Era: The mediation role of well-being

C. Laranjeira[1,2*] and A. Querido[1,2]

[1]School of Health Sciences and [2]ciTechCare, Polytechnic Institute of Leiria, Leiria, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.536

Introduction: In recent years, more and more researchers have found positive psychological changes after experiencing stressful events. When people are exposed to stressful events, a sense of hope and psychological well-being, as significant positive psychological traits, can lessen the negative effects of psychological imbalance and help them cope with their worries in life in a more positive way, effectively promoting and protecting their mental health
Objectives: This study aims to examine the mediating role of well-being in the relationship between people's perception of hope and mental health.
Methods: The present research was performed using a convenience (or snowball) sampling method obtained in the context of the Hope Barometer research program in 2023. Inclusion criteria were being an adult (aged ≥ 18 years); providing e-consent; having internet access; and understanding the Portuguese language. An online survey including information sheet, demographic questions, and three instruments, namely: Dispotional Hope was measured through the Perceived Hope Scale [PHS]; Mental health status was evaluated by General Anxiety Disorder-7itens; and, well-being measured by the Mental Health Continuum Short Form (MHC-SF). We employed the PROCESS macro for SPSS (model 4: mediation analysis) to evaluate our model.
Results: The most frequently reported demographic categories were female (n=402), married (n = 206), have children (n = 344), graduated (n = 442), and with religious/spiritual affiliation (n = 400). The mean age was 47.72±11.86 years old. Dispositional hope were significantly and positively correlated with mental health. We conducted a mediation analysis to examine whether mediates the relationship between dispositional hope and mental health. The indirect effects for hedonic well-being (β = 0.28; 95% CI [0.02, 0.36]), psychological well-being (β = 0.14; 95% CI [0.06, 0.19]), and social well-being (β = 0.06; 95% CI [0.008, 0.073]) were all significant, indicating a mediating effect.
Conclusions: Given the COVID-19 pandemic and its consequences have caused a variety of psychological distress such as fears, worries, and anxiety among people worldwide, this study underlies the mechanism between positive psychological resources such as perceived hope and well-being of individuals during the times of crisis of COVID-19 affects their mental health.

The weight of office? A systematic scoping review of mental health issues and risk factors in elected politicians across democratic societies

A. Smith[1*], S. Hachen[2], A. Weinberg[3], P. Falkai[4], S. Guttormsen[5] and M. Liebrenz[1]

[1]Department of Forensic Psychiatry; [2]University of Bern, Bern; [3]School of Health and Society, University of Salford, Salford, Switzerland; [4]LMU Clinic, Ludwig Maximilian University of Munich Public university in Munich, Germany, Munich, Germany and [5]Institute of Medical Education, University of Bern, Bern, Switzerland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.537

Introduction: The mental health status and capacity to govern of democratically-elected politicians have become significant topics of interest, which have attracted speculation in the media and beyond. In fulfilling demanding and high-stress positions, politicians could encounter distinctive risk factors that may harm their mental well-being, yet existing research literature about this topic remains underexplored.
Objectives: This scoping review aimed to systematically examine the breadth of available evidence on mental health issues and risk factors affecting democratically-elected politicians and to identify future research needs.
Methods: Using pre-defined eligibility criteria based on JBI guidelines, a systematic keyword search was conducted in May 2024 of MEDLINE, Scopus, and APA PsycNet, supplemented by snowballing techniques. Only studies reporting primary, empirical evidence on mental ill-health or risk factors with adverse psychological correlates from serving politicians in "Full" or "Flawed" democracies (per the Democracy Index) were included from 1999-2024. Titles and abstracts were screened and the full-text of potentially eligible literature was assessed before data extraction and synthesis.
Results: Eighteen sources met the eligibility criteria, cumulatively encompassing ~3,500 politicians across seven democracies, namely: Australia, Canada, the Netherlands, Norway, New Zealand, the United Kingdom, and the United States. Four sources (22.2%) explored general psychopathology trends, revealing varying but sizeable rates of mental ill-health and high-risk alcohol consumption. The other fourteen studies (77.8%) provided evidence on risk factors; twelve underlined the psychological toll of violence and two investigations highlighted the injurious effects of specific occupational conditions. Notably, exposure to violence often precipitated detrimental mental health outcomes, with certain data indicating a disproportionate impact on female officeholders.
Conclusions: Existing research literature suggests that democratically-elected politicians face considerable mental health challenges,

especially from the effects of violence. However, there are notable research gaps with a paucity of reliable prevalence estimates, intervention studies, and work on national leaders. Equally, the underrepresentation of numerous democratic countries accentuates the need for a more diverse evidence-base to better support the mental wellbeing of politicians worldwide.

Rethinking access to psychological treatment protocols in mental health research

C. Blithikioti[1]*, G. Tomei[1], F. Visconti[1], I. G. Gómez[2] and I. A. Cristea[1]

[1]General Psychology, University of Padova, Padova, Italy and [2]Psychology, University of Loyola, Seville, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.538

Introduction: Open access to psychological treatment manuals is critical for advancing research and clinical practice, particularly in low- and middle-income countries, where access to mental health care is scarce. Despite growing recognition of the need for freely available manuals to ensure replicability, transparency, and wider dissemination of evidence-based interventions, open and free access to intervention manuals remains limited.
Objectives: We aimed to quantify the availability of protocols and manuals for psychological interventions used in randomized clinical trials (RCTs) for severe mental disorders. This research is part of the broader European Research Council – funded project DECOMPOSE, in which we employ a systematic and reproducible approach for decoding, classifying, and evaluating the active ingredients of psychological interventions.
Methods: Using recent network meta-analyses of RCTs, we collected psychological interventions for psychotic, bipolar, substance use, eating, and borderline personality disorders. We attempted to retrieve intervention protocols and manuals directly from trial publications or their published protocols and referenced manuals. If the protocols or manuals were not accessible, we contacted the study authors to request the materials.
Results: We identified a total of 259 RCTs, but only 18 had published protocols. Of the 71 RCTs pre-registered on platforms such as ClinicalTrials.gov, only 5 provided an adequate description of the psychological treatment components, all of which overlapped with already published protocols. To retrieve missing materials, we contacted 450 authors from 241 RCTs. We received positive responses from 75 RCTs, negative responses from 55 RCTs, and no replies from 100 RCTs. We were not able to retrieve contact information for the authors of 11 RCTs.
Of the 75 positive responses, we obtained the complete requested materials for only 47 trials. In the remaining cases, we were instructed to purchase the manuals (n=11), provided with only partial materials (n=4), or given additional references that were not the full intervention manual (n=13). Negative responses included the trial being too old or no authors' access to the materials (n=22), commitment to send the materials without further follow-up (n=8), suggesting the paper as the sole available resource (n=11), and various other reasons (n=14)
Conclusions: Our findings reveal a significant lack of freely available intervention manuals, limiting the implementation and replicability of psychological treatments. Coordinated action is needed to ensure open access to these materials for more replicable research, wider dissemination of results, and improved access to evidence-based mental health care.

The Positive Writing on Mood States: Empirical Study

I. S. Lancia[1]*, G. M. Festa[1,2], A. Attouchi[1], F. De Pasquale[1] and M. Manganozzi[1]

[1]Interdisciplinary Institute of Advanced Clinical Training «IACT» and [2]Pontifical Faculty of Educational Sciences «AUXILIUM» , Rome, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.539

Introduction: Positive writing (PW) consists in a written treatment of real or imagined events, processed with a positive connotation. The technique has been proven useful and effective for increasing psychological well-being. It derives from the expressive writing (EW) methodology developed by James Pennebaker.
Objectives: The objective of this study is to analyze the effects of positive writing (PW) in a group of healthy subjects. The psychological variables measured following the application of PW are six mood states: tension, depression, anger, vigor, fatigue and confusion. These are preliminary data from work that is still in progress.
Methods: Two groups were randomly formed (one experimental and one control) and wrote for 3 consecutive days on different topics. The experimental group wrote for 20 minutes a day about the most rewarding experience of their life, while the control group described, again for 20 minutes a day, a topic with a low emotional connotation (description of their home). Three administrations (baseline, 3-day follow-up and 10-day follow-up) of the POMS (Profile of Mood States) psychological test were carried out on study participants.
A statistical analysis such as analysis of variance (2-way ANOVA for repeated measures) was used to analyze the effects of positive writing in relation to the different parameters considered, between the groups (Experimental Group vs Control Group) in three different times (baseline, 3 days, 10 days).
Results: Statistically significant decreases were recorded in the experimental group in confusion (Factor C) in the 10-day measurement (7.44 VS 5.00 $p < 0.01$) and in fatigue (factor S) (5, 94 VS 3.88; $p < 0.05$).
Conclusions: These data demonstrate how positive writing can lead to beneficial psychological effects. In particular, this study examined the effects of writing about one's real life experiences and highlighted beneficial psychological/cognitive effects (decreased confusion) and psychophysical (decreased feelings of fatigue). Focusing attention on one's positive experiences therefore produces improvements on a cognitive level for the sensations that concern clarity and linearity of thought and reduction of feelings of psycho-physical fatigue.

Changes of heart rate variability and hemodynamics within the frontal cortex in response to face emotional stimulation

B. Nam[1]*, S. A. Chung[2], H. Hwang[2], H. J. Kim[2], J. Hong[2], S. M. Kim[2] and D. H. Han[2]

[1]Dr. Nam's Psychiatric Clinic, Chungju and [2]Chung Ang University Hospital, Seoul, Korea, Republic Of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.540

Introduction: There is an increasing demand for alternative evaluation tools capable of providing objective assessments or highlighting differences. Functional near-infrared spectroscopy (fNIRS) and heart rate variability (HRV) are frequently employed as biomarkers for assessing emotional status.
Objectives: This study hypothesizes that emotional expressions, particularly unpleasant emotions and their variations in adolescents, are associated with changes in heart rate variability and frontal lobe activity.
Methods: A total of 55 adolescents participated in this study. Following the completion of clinical scales, assessments of both HRV and fNIRS in a resting state were conducted for all participants for 200 seconds. After a 10-second rest, HRV and fNIRS assessments were performed during a positive emotional perception test for 192 seconds. Following a 30-second rest, the same procedures were repeated during a negative emotional perception test.
Results: The correction rate of unpleasant emotional perception negatively correlated with HRV measures (unpleasant-HF, unpleasant-SDNN) and positively with pleasant-RMSSD. Additionally, it positively correlated with the ΔaccHBO2 within the left dorsolateral prefrontal cortex (DLPFC). Conversely, the correction rate of pleasant emotional perception negatively correlated with increases in ΔaccHBO2 within the left DLPFC. Both unpleasant-SDNN and unpleasant-HF negatively correlated with ΔaccHBO2 within the left DLPFC.
Conclusions: The perception of negative emotions in adolescents is associated with individual levels of depression and anxiety. Furthermore, the perception of negative emotions significantly correlates with changes in HRV and activity within the left DLPFC. There is also evidence suggesting a link between changes in HRV and brain activity in response to the perception of negative emotions.

Adapting Tree of Life Group Therapy for Vietnamese Patients with Severe Mental Disorders: A Qualitative Exploration of Treatment and Recovery Perspectives

L. T. Nguyen[1]* and H. T. T. Hoang[1]

[1]Department of Outpatients, Hanoi Mental Hospital, Hanoi, Viet Nam
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.541

Introduction: Severe mental disorders, characterized by their progressive course, early onset, and persistent symptoms, pose significant challenges to patients' well-being and psychosocial functioning. Despite the growing recognition of the importance of comprehensive treatment, psychological therapies remain underutilized in this population in Vietnam. The Tree of Life therapy, a low-cost, evidence-based, and culturally adaptable intervention, offers a holistic perspective on mental health recovery through personal growth, enhanced coping skills, and social connectedness. This study aimed to explore the therapeutic potential of the Tree of Life group therapy for inpatients with severe mental disorders at Hanoi Mental Hospital.
Objectives: 1) To understand the experience of participating in the Tree of Life therapy group for inpatients with severe mental disorders; 2) To explore the perspectives of patients on the hospitalization, inpatient treatment process, their self-perception, life goals and resources before and after participating in the group
Methods: Using qualitative methods, we interviewed 30 inpatients about their experiences before and after participating in the therapy. The Tree of Life group was conducted through four 1-hour sessions guided by the original protocol (Ncube, 2006). The study design follows a qualitative approach. After collection, the data was transcribed, coded, and stored as online text. We chose thematic analysis using MAXQDA 24 software for data analysis.
Results: Regarding the Tree of Life group therapy experience, prominent themes emerged, including positive group interactions, relevant content, enhanced health and well-being, therapeutic engagement promotion, and memorable session components. When examining patients' perspectives on hospitalization, treatment, recovery, self-description, hopes and dreams, and resources, a strong emphasis on family stood out. The family theme was then analysed further to identify subthemes: Family members were perceived as gatekeepers to treatment, sources of love and support, motivations for recovery, active participants and decision-makers in future life plans.
Conclusions: The pilot qualitative study demonstrates the potential therapeutic efficacy of Tree of Life group therapy for patients with severe mental disorders. The findings also highlight the critical role of the family in supporting patients with severe mental disorders and underscore the importance of involving family members in the treatment process in the Vietnam context. However, further randomised controlled trials are required to establish the therapy's effectiveness on a broader scale and provide robust evidence for clinical implementation.

Electrophysiological Signature of Emotional Processing in Participants with High Traits of Rumination During a Mood-Induction Task

C. Spironelli[1,2]*, Z. Romeo[3], F. Fusina[1], S. Messerotti Benvenuti[1] and A. Angrilli[1]

[1]Department of General Psychology, University of Padova; [2]Padova Neuroscience Center, University of Padova and [3]Neuroscience Institute, National Research Council (CNR), Padova, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.542

Introduction: Past studies found lack of left frontal asymmetry in major depressive disorder (MDD) patients, also during task execution, probably depending on thought disorders associated to MDD. Indeed, individuals suffering from depressive mood are more likely to develop

specific symptoms, i.e., rumination (R) (Thomsen, 2006) and perseverative thoughts (PT). According to Martin & Tesser (1996), rumination could be defined as *"[…] a class of conscious thoughts that revolve around a common instrumental theme and that recur in the absence of immediate environmental demands requiring the thoughts"*. Following this definition, this symptom can be represented along a continuum ranging between healthy individuals and patients with full-blown mood disorder.

Objectives: The present study aimed at investigating the psychophysiological markers underlying the risk to develop mood disorders, in a community sample selected for two important psychiatric transdiagnostic domains, i.e., perseverative thoughts and ruminations (PT/R).

Methods: In order to prompt a rumination state, we developed a new mood induction paradigm based on presentation of brief, validated videoclips able to evoke sadness, psychological sufferance and feelings of loss. Subjective reports and high-density EEG data from 20 students with high ($\geq 80^{th}$) and 20 with low ($\leq 20^{th}$ percentile) PT/R were collected. Subjective data analyses included self-perceived valence and arousal for 'love abandonment', 'loneliness' and 'city documentary' (i.e., neutral) clips. sLORETA source analyses on EEG bands were carried out to unmask the cortical areas involved in rumination.

Results: Regardless of group, emotional clips elicited greater valence and arousal scores than neutral videos. Between-group sLORETA analysis revealed greater delta and theta activity in low vs. high PT/R participants in left superior parietal lobule during viewing of 'love abandonment' clips. Within-group analysis carried out in low PT/R participants showed that, compared with neutral clips, the 'love abandonment' and 'loneliness' conditions elicited greater alpha activity in superior (left) and middle (right) frontal gyri, respectively. On the contrary, high PT/R participants showed similar right (pre)cuneus alpha increase, regardless of emotional content.

Conclusions: Results suggest a decreased sensitivity to negative videoclips in high PT/R individuals, together with the loss of the specialized frontal hemispheric valence-dependent asymmetry that is typically found in low PT/R participants.

Assessing the impact of psychological support on healthcare workers in conflict zones: a 5-Session intervention in North Kivu and Ituri

E. Dozio[1]* and V. Wamba[2]

[1]Mental Health and Psychosocial Support, Action contre la Faim, Paris, France and [2]Mental Health and Psychosocial Support, Action contre la Faim, Goma, Congo, The Democratic Republic of the
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.543

Introduction: North Kivu and Ituri in the Democratic Republic of the Congo (DRC) are among the provinces most severely affected by humanitarian needs. The security situation is highly unstable, with over 530,000 people displaced. Those remaining face urgent needs, and the conflict has severely impacted their mental health. An assessment of healthcare staff in local centers revealed significant distress due to both their exposure to patients in crisis and the surrounding violence and insecurity.

Objectives: The aim of the protocol developed and proposed to healthcare staff was to implement preventive and curative phycological support actions designed to address all the psychosocial risks identified, as well as to alleviate emotional distress, improve well-being and strengthen the resilience mechanisms of healthcare centre staff.

Methods: A 5-session protocol was proposed to healthcare staff. The sessions focused on psychological distress specific to professional situations in the context of conflict and humanitarian emergencies: vicarious trauma and self-help strategies using emotional regulation exercises. We measured several dimensions of participants' psychological and professional well-being at the start and end of the programme: the PCL-5 to assess post-traumatic stress symptoms, the HADS to measure levels of anxiety and depression, the Maslach Burnout Inventory (MBI) to assess three dimensions of burnout: emotional exhaustion, depersonalisation and personal fulfilment. Finally, the ProQoL scale was used to assess participants' quality of working life.

Results: Analyses of the scores differences between pre and post intervetion, among a pre-sample of 65 participants (21% women; 78.5% men) showed significant improvements. Anxiety and depression levels decreased significantly (HAD-A: t = - t = 7.71, $p < 0.001$; HAD-D: t = 7.30, $p < 0.001$). On the MBI, participants showed a significant reduction in emotional exhaustion (t = 5.83, $p < 0.001$) and depersonalisation (t = 8.85, $p < 0.001$) and an increase in the sense of personal accomplishment (t = -5.12, $p < 0.001$). The results also show a clear reduction in post-traumatic stress symptoms (PCL-5: t = 8.64, $p < 0.001$). On the ProQoL scale, compassion satisfaction also increased significantly (t = -5.70, $p < 0.001$), indicating that carers feel more gratified by their role despite the challenges they face. Secondary traumatic stress (t = 5.38, $p < 0.001$), and burnout (t = 2.82, p = 0.006)., although significantly reduced, remain areas of concern.

Conclusions: The intervention had significant positive effects on several dimensions of the psychological and professional well-being of healthcare workers, contributing to better stress management, increased satisfaction, and reduced burnout. These results highlight the importance of implementing support programs for healthcare professionals working in challenging contexts.

Psychiatric and cognitive characterization of Jacobsen syndrome (Del11q)

A. Garriz-Luis[1,2]*, E. Rodríguez-Toscano[1,2], M. Burdeus-Olavarrieta[1], C. Arango[1,3], M. Parellada[1,3], N. Logo[1] and C. M. Díaz-Caneja[1,3]

[1]Department of Child and Adolescent Psychiatry, Institute of Psychiatry and Mental Health; [2]School of Psychology and [3]School of Medicine, Universidad Complutense, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.544

Introduction: Jacobsen Syndrome (JS), or 11q Deletion Syndrome, is a rare genetic disorder affecting approximately 1 in 100,000 births, with a female-to-male ratio of 2:1 (Grossfeld *et al.* Am J Med Genet A. 2004; 129A(1):51-61). It is caused by a deletion on chromosome

11's long arm, leading to diverse clinical features, affecting mainly the immune and cardiac systems (Dalm *et al.* J Clin Immunol. 2015; 35(8):761-8). Core neuropsychiatric symptoms include intellectual disability, psychomotor delays and distinctive physical traits. Recent reports highlighted attention deficits and autism-like characteristics (Akshoomoff *et al.* Genet Med. 2015; 17(2):143-8). Although previous studies identified varied cognitive profiles in JS, most focused on medical features, and a detailed psychiatric and cognitive characterisation is lacking.
Objectives: This study aims to describe and analyse the psychiatric and cognitive profiles of individuals with JS as well as its associations, within a Spanish sample.
Methods: Twenty-nine participants aged 2 to 45 years were recruited from the Spanish association "11q España". Psychiatric data were collected through interviews with parents and cross-referenced with medical reports, and behavioural symptoms were assessed using the Child Behavior Checklist (CBCL). Cognitive functioning was evaluated using Wechsler scales and the Merrill-Palmer-Revised scale.
Results: The cohort's average age was 12 years, with a female majority (68.9%). Psychiatric or neurodevelopmental comorbidities were present in over half (51.72%), with ADHD being the most common. According to the CBCL, 54.4% had internalising problems, and 54.5% had externalising problems. The average Intellectual Quotient (IQ) was 50.18, and the mean Developmental Quotient 36. When grouped by disability, 17.3% had borderline functioning, 17.3% mild, 21.7% moderate, 26% severe, and 17.3% profound ID. Higher IQ was associated with increased depression diagnoses and anxious/depressed symptoms.
Conclusions: This study provides a detailed neurocognitive profile of individuals with JS, confirming its heterogeneous presentation. Psychiatric comorbidities, especially ADHD, were common, and cognitive functioning ranged from borderline to profound ID, with no cases of normal cognition. Notably, participants with higher cognitive abilities were more prone to depression, highlighting the need for targeted mental health support tailored to individuals with JS.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.545

Introduction: Nearly two-thirds of individuals with a mental disorder start experiencing symptoms during adolescence or early adulthood, and the onset of a mental disorder during this critical life stage strongly predicts adverse socioeconomic and health outcomes. Subthreshold manifestations of Autism Spectrum Disorders (ASD), also called autistic traits, are known to be associated with a higher vulnerability to the development of other psychiatric disorders. Current psychopathological research has pointed out the shortcomings of a categorical approach to mental illnesses (e.g., the concept of comorbidity) whilst a dimensional approach allows the description of patients across multiple syndrome dimensions that, in turn, constitute broad spectra of interrelated psychopathologies.
Objectives: This study aimed to assess the presence of autistic traits in a population of young adults seeking specialist assistance, and to evaluate the study population across various psychopathological domains in order to determine their links with autistic traits.
Methods: We recruited a sample of 263 adolescents and young adults referring to a specialized outpatient clinic, and we administered them several self-report questionnaires for the evaluation of various psychopathological domains: the *Autism Quotient,* the *Ritvo Autism and Asperger Diagnostic Scale-Revised*, RAADS-R, the *Empathy Quotient,* EQ, the *Sensory Perception Quotient – Short Form,* SPQ-SF35, the *Beck Depression Inventory*, BDI-II, the *State-Trait Anxiety Inventory,* STAI-Y1 and Y2, the *Eating Attitude Test-26 items*, EAT-26, the *Prodromal Questionnaire–short version*, PQ-16, the *Personality Inventory for DSM-5*, PID-5-BF, the *Pathological Narcissism Inventory*, PNI. We then conducted a cluster analysis based on the prevalence of autistic traits (AQ, RAADS-R), empathy (EQ) and sensory sensitivity (SPQ-SF35) scores.
Results: The cluster analysis identified three distinct groups in the sample: an autistic traits (AT) cluster (22.43%), an intermediate cluster (45.25%), and a no-AT cluster (32.32%). Moreover, subjects with higher autistic traits exhibited significantly greater symptomatology across multiple psychopathological domains, including mood, anxiety, eating disorders severity, psychotic symptoms, and personality traits such as Detachment and Vulnerable Narcissism.
Conclusions: The study highlights the importance of identifying autistic traits in young individuals struggling with mental health concerns, and suggests a relationship between autistic traits and greater overall psychopathological burden. Additionally, the findings underscore the necessity of adopting a dimensional approach to psychopathology, in order to better understand the complex interplay of different psychiatric symptoms and facilitate tailored interventions.

Unveiling Neuropsychiatric Phenomena: The Impact of Linguistic Precision on Clinical Insight

V. H. Santos[1,2]*, F. M. Tehrani[3], N. Castro[4], B. Sousa[1], Z. C. e Sá[1], T. Carvalhão[1] and S. Fontes[1]

[1]Department of Psychiatry and Mental Health, Cova da Beira Local Health Unit; [2]Faculty of Health Sciences, University of Beira Interior, Covilhã, Portugal; [3]Mental Health Services in the Capital Region of Denmark, Child and Adolescent Mental Health Center, Copenhagen, Denmark and [4]Department of Psychiatry and Mental Health, Viseu Dão-Lafões Local Health Unit, Viseu, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.546

Introduction: Precision of language in neuropsychiatry is vital for the accurate understanding of complex psychopathological

phenomena. Many expressions used in psychiatry, especially those of German origin, reflect nuanced descriptions of patient behaviors, cognitive impairments, and emotional states that are not easily captured by modern terms. These linguistic tools provide a window into the intricate dynamics between the mind and body, helping clinicians interpret and navigate the subtleties of neuropsychiatric conditions.
Objectives: This review aims to explore how specific expressions in neuropsychiatry, derived from clinical German terminology, contribute to a deeper understanding of patient experiences and enhance the precision of clinical assessment. By examining these linguistic elements, the paper seeks to illustrate their relevance in diagnosing and treating neuropsychiatric disorders, particularly where conventional language falls short.
Methods: Through a conceptual analysis, this review delves into the historical development and clinical application of several key terms originating in German psychiatry. Terms such as "Gegenhalten," which describes paradoxical resistance in catatonia, and "Weltschmerz," a term encapsulating existential despair, are examined within clinical contexts. The review also discusses other terms such as "Mitgehen," referring to automatic obedience, and "Vorbeireden," which highlights disorganized speech patterns. The review draws upon classical psychiatric literature and modern clinical observations to demonstrate how these terms inform diagnosis and treatment strategies.
Results: The use of these specific linguistic constructs offers neuropsychiatrists valuable insights into the subjective experiences of patients, often highlighting behaviors and emotional states that would be otherwise overlooked. For example, "Gegenhalten" allows for the differentiation of motor dysfunction in catatonia, while "Weltschmerz" provides a unique framework for understanding a type of depression that transcends typical diagnostic boundaries. Similarly, "Vobeirreden" aids in the recognition of cognitive disorganization, and "Mitgehen" underscores deficits in volitional control. These terms provide clinicians with greater clarity and precision in diagnosis and therapeutic approaches, bridging the gap between patient experiences and clinical evaluation.
Conclusions: This review underscores the importance of language in the accurate interpretation of neuropsychiatric disorders. It demonstrates how these terms enrich the diagnostic process and offer deeper clinical insights into patient behaviors and symptoms. The nuanced language of neuropsychiatry not only enhances understanding but also serves as a tool for more targeted and effective interventions. Ultimately, this approach encourages clinicians to consider the broader impact of linguistic precision in both diagnosis and treatment planning.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.547

Introduction: The Pain Catastrophizing Scale (PCS) is a widely used self-report tool for evaluating pain-related catastrophizing. In response to the need for more efficient diagnostic tools in clinical environments, the PCS has been shortened from 13 to 4 items in developing the brief version.
Objectives: The objectives of this study were: (1) to examine the factor structure of a Korean-language version of the brief K-PCS and (2) to assess the reliability and validity of the brief K-PCS.
Methods: A total of 131 patients seeking treatment at a tertiary pain center in Daejeon, Korea, participated. Confirmatory factor analysis (CFA) with maximum-likelihood estimation was performed to evaluate the adequacy of the one-factor model. Cronbach's alpha coefficients and Pearson correlations were calculated to investigate internal consistency and 2-week test-retest stability of the brief K-PCS, respectively. For concurrent validity, Pearson correlations were also calculated to examine the relationships between the brief K-PCS and various outcome measures.
Results: The confirmatory factor analysis confirmed the adequacy of the brief K-PCS's unifactor structure, indicated by excellent fit indices (CFI = .999, TLI = .996, SRMR = .039). The brief K-PCS exhibited high internal consistency (Cronbach's α = .83). Test-retest correlations over a 2-week interval was .744 ($p < .001$), indicating high stability. For concurrent validity, the brief K-PCS showed significant positive correlations with measures of depression, fearful thinking, physical response, avoidance, and pain-related anxiety ($p < .001$), and significant negative correlations with quality of life measures, including physical, psychological, social relationships, environmental, and general quality of life ($p < .001$).
Conclusions: The brief K-PCS is a reliable and valid tool for assessing pain catastrophizing in a Korean patient sample with chronic pain.

Personality and Personality Disorders

EPP231

The Role of Mood Stabilizers and Antipsychotics in the Treatment of Borderline Personality Disorder

J. F. Barbosa[1]*, D. M. Silva[1], B. Leal[1], A. Lourenço[1], A. C. Nunes[1], M. A. Silva[1], C. Oliveira[1] and M. Nascimento[1]

[1]Hospital Júlio de Matos, ULS São José, Lisbon, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.548

Introduction: The treatment of Borderline Personality Disorder (BPD) presents a clinical challenge in many ways, as the current recommended psychotherapies are often insufficient or unavailable. As of today, no pharmacological treatment has been approved by regulatory agencies for the treatment of BPD, even though up to 96% of these patients receive at least one psychotropic medication. Some professional societies cautiously recommend the off-label and symptom-targeted use of psychotropic agents as part of a multimodal approach, whereas others recommend its use only in the event of an acute crisis.
Objectives: Conduct a non systematic review of literature regarding the efficacy of mood stabilizers (MS) and antipsychotics (AP) in the treatment of patients with BPD.
Methods: A search in the PubMed database was performed with the terms *borderline*, *behaviour* and *mood stabilizer* or *antipsychotic* or *pharmacological*, filtered for reviews, systematic reviews and meta-analysis over the last 20 years.
Results: The efficacy of pharmacotherapies for the treatment of BPD is limited to improvement of individual symptoms but not of global functioning nor the severity of the condition overall, although the evidence is of very low certainty. For affective dysregulation and impulsive-behavioural dyscontrol, the highest efficacy emerged for MS, as AP shows a lower yet significant effect size. Both drug classes seem to improve symptoms of anger, with evidence suggesting a much larger (and significant) effect-size for aripiprazole compared to other AP. For cognitive-perceptual symptoms, only AP proved to be effective, showing higher effect-size in longer trials, which suggests their slowly progressive efficacy on this symptom dimension. Although many studies suggest a superior anti-suicide effect of clozapine in schizophrenia, the evidence is very uncertain about the effect of any medication compared with placebo on self-harm and suicide-related outcomes in patients with BPD, indicating little to no effect. There appears to be no significant difference between pharmacotherapy and placebo in terms of dropout rates, but there is insufficient data regarding drug tolerability in these patients.
Conclusions: In congruence with some clinical practice guidelines, pharmacotherapy can be used to target specific core-symptoms on BPD, even though evidence on its efficacy is of very low certainty and limited to the improvement of individual symptoms but not the overall condition. Mood stabilizers and antipsychotics can have a positive effect on affective dysregulation, anger and impulsive-behavioural dyscontrol, and antipsychotics proved to be effective for cognitive-perceptual symptoms.

The Hidden Burden: Systemic and Individual Factors Driving Extensive Care in Personality Disorders

P. Sand[1] and F. G. Di Leone[2,3]*

[1]Department of psychology, University of Gothenburg; [2]Affective psychiatry, Sahlgrenska Univeristy Hospital and [3]Institute of Neuroscience and Physiology, University of Gothenburg, Gothenburg, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.549

Introduction: Individuals with personality disorders (PD) are overrepresented in emergency psychiatric settings, leading to both frequent and prolonged hospitalizations, compulsory care and high healthcare costs.
Objectives:
(1) To delineate the extensive care needs of participants, (2) To identify commonalities in their life situations, comorbidities, and treatment interventions, and (3) To investigate patient experiences with the healthcare system to uncover precipitating and contributing factors to extensive care needs.

Methods: The quantitative study utilized a descriptive cross-sectional design, drawing on data from 61 individuals diagnosed with PD who exhibited extensive care needs, operationally defined as having made five or more visits to the emergency department, at least three hospitalizations, or a total of 60 hospitalization days during 2023. The qualitative study involved in-depth interviews with 11 of these individuals, analyzed using interpretative phenomenological analysis (IPA) to explore patient experiences and needs.
Results: The findings indicate that individuals with comorbid conditions experienced significantly more frequent and prolonged hospitalizations. However, there was no significant difference in the number of emergency department visits between the two groups. Qualitative insights revealed four main themes with two focusing on precipitating factors, and two addressing perpetuating factors. The results indicated that emergency department visits were frequently driven by emotional distress and social isolation. Patients described their treatment experiences as impersonal and lacking direction, with frequent medication adjustments resulting in adverse effects and heightened feelings of hopelessness.
Conclusions: The study highlights that extensive care needs among individuals with personality disorders (PD) arise from a combination of high psychopathological burden and social marginalization. Many high-care consumers rely on hospitalization as their primary support, reflecting a psychiatric system ill-equipped to meet their complex needs. This mismatch leads to patient dissatisfaction and a revolving-door effect, where repeated hospitalizations further detach patients from their social environments, increasing the risk of continued high care consumption. Overmedicalization and frequent hospitalizations exacerbate social isolation, fueling a cycle of increased care dependency. To address these challenges, the study proposes targeted interventions, including: (1) early assessment of risk factors such as social isolation, comorbid conditions, and lack of social roles, (2) promoting alternative forms of hospitalization, (3) implementing a stepped care model for crisis management, and (4) improving comorbidity management and medication oversight.

Repurposing Clozapine: An Off-Label Approach to Target Impulsivity, Emotional Dysregulation, and Suicidality in Borderline Personality Disorder

B. Firenzuoli[1]*, A. Cuomo[1], E. Mariantoni[1], A. Morrone[1], P. Carmellini[1], S. Pardossi[1], A. Pierotti[1] and A. Fagiolini[1]

[1]Molecular Medicine, University of Siena, Siena, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.550

Introduction: Clozapine, traditionally prescribed for treatment-resistant schizophrenia, has shown potential for off-label use, particularly in affective and personality disorders characterized by severe impulsivity, nonsuicidal self-injury (NSSI), and suicidality (Delgado *et al* 2020*, Journal of psychiatric research, 125*, 21-27). Emerging evidence suggests that clozapine's unique pharmacodynamic profile (serotonergic activity and high affinity for D4R, α1R, H1R) may contribute to reducing aggression and impulsivity and offer therapeutic benefits for borderline personality disorder (BPD). This is particularly relevant given the high suicide risk in BPD patients, with an estimated annual rate up to 10%, 50 times higher than the general population. Despite this, current treatment guidelines for BPD typically limit pharmacological interventions in favor of psychotherapeutic approaches (Pascual JC *et al* Int Clin Psychopharmacol. 2010, 25(6), 349-55). However, clozapine's ability to modulate impulsivity and emotional dysregulation could provide a valuable adjunct in the treatment of this complex disorder.
Objectives: To evaluate the efficacy of clozapine in reducing impulsivity, emotional dysregulation, and suicidality in patients with BPD.
Methods: The study cohort consisted of 47 patients (29 women) with a mean age of 28 years (IQR: 22-44), all diagnosed with BPD resistant to previous pharmacological treatments. Clozapine was introduced after a comprehensive risk-benefit assessment. At baseline, 96% of patients were taking mood stabilizers or anticonvulsants, 87% were taking SSRI/SNRI antidepressants, 81% were taking antipsychotics, and 66% were taking other medications such as benzodiazepines or gabapentinoids. Clinical assessments using the RIPoST-40, MOAS, and Columbia scales were administered at baseline, one week (T1), one month (T2), and three months (T3). Data were analyzed using repeated measures ANOVA and Friedman's test with significance set at $p<0.01$ after Bonferroni correction.
Results: Significant reductions in all scores were observed at T3: RIPoST-40 scores decreased by 40.15% ($p<0.0001$), MOAS by 58% ($p<0.0001$), Columbia Scale scores by 70.20% ($p<0.0001$). At month 3, clinical response, defined as a ≥50% reduction in scores, was achieved by 11% of patients on the RIPoST-40, 70% on the MOAS, and 94% on the Columbia Scale.
Conclusions: Clozapine demonstrated significant reductions in impulsivity, emotional dysregulation, and suicidality in patients with BPD, with rapid improvements observed within the first week and sustained through 3 months. These findings suggest that clozapine, in combination with psychotherapy, may be an effective treatment strategy for the most severe symptoms of BPD. Further prospective studies with larger cohorts are needed to validate these preliminary results and to assess the long-term safety and efficacy of clozapine in this population.

Disclosure of Interest: None Declared

EPP234

Association of anterior thalamic radiations alterations with impulsivity in patients with borderline personality disorder

L. Franczak[1]*, P. Podwalski[1], B. Dawidowski[1] and J. Samochowiec[1]

[1]Department of Psychiatry, Pomeranian Medical University, Szczecin, Poland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.551

Introduction: The anterior thalamic radiations refers to fiber pathways that connect the anterior nuclear group of the thalamus and the midline nuclear group of the thalamus with the frontal cortex – a region linked to complex cognitive processes such as impulse control and decision making abilities. Typically characterized by risky behaviors without prior consideration or planning impulsivity is a hallmark feature of Borderline Personality Disorder (BPD). Structural alterations in the anterior thalamic radiations may disrupt cognitive functions and potentially exacerbate impulsivity, in individuals diagnosed with BPD.
Objectives: The objective of this research is to evaluate whether individuals with borderline personality disorder (BPD) exhibit abnormalities in the anterior thalamic radiations (ATR) compared to healthy controls (HC) and their potential association with impulsivity.
Methods: This research conducted an analysis using diffusion tensor imaging (DTI) being conducted on 90 individuals (aged between 18 and 43), fifty five individuals diagnosed with borderline personality disorder compared to forty five healthy individuals. The study utilized fractional anisotropy (FA) to investigate the integrity of the thalamic radiation (ATR). Impulsivity was measured through Eysenck's Impulsivity Inventory questionnaire. The study examined differences in FA values among the two groups. Looked into the potential correlation, between ATR integrity and levels of impulsivity.
Results: The BPD group had statistically significantly higher scores on the impulsivity subscale than the HC group ($U = 1672.5$, $p < 0.001$), which persisted after correction for multiple comparisons ($p < 0.001$). No statistically significant between-group differences were found on the venturesomeness ($U = 889$, $p = 0.513$) and empathy ($U = 1097.5$, $p = 0.276$) subscales. No statistically significant differences between groups were observed in the right ATR ($U = 849$, $p = 0.326$). Only a trend for higher FA values in the left ATR in HC was observed ($U = 760$, $p = 0.084$). After correction for multiple comparisons, the trend disappeared ($p = 0.168$). There were no statistically significant correlations of mean FA with IVE subscales scores, regardless of stratification.
Conclusions: Despite past research suggesting a link between ATR alterations and impulsivity, this study found no such correlation in individuals with BPD. This highlights the need for further research, using imaging methods and larger samples, to better understand the neurological basis of impulsivity in BPD.

Ten-year prescription trend of second-generation antipsychotics in adult psychiatric patients from 2014 to 2023 – a territory-wide population-based study

S. Pan[1]*, B. P. Or[1], T. M. Li[1], N. Y. Chan[1], T. C. Yip[2], V. W. Wong[2], Y. K. Wing[1] and J. W. Chan[1]

[1]Department of Psychiatry and [2]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, Hong Kong

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.552

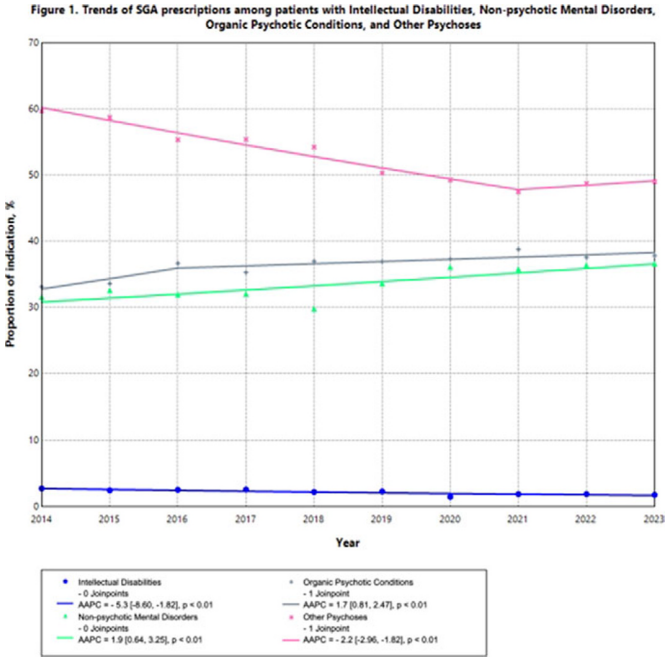
Introduction: Second-generation antipsychotics (SGAs) have been increasingly used as off-label treatments for non-psychotic illnesses, there is a lack of updated data to describe its prescription among psychiatric populations.

Objectives: This study aims to describe the most recent ten-year trend of SGA prescriptions and to identify the probable psychiatric diagnoses associated with the prescription among adult psychiatric patients in Hong Kong.

Methods: All patients aged 18 or older who had a psychiatric diagnosis and were initiated on an SGA based on the population-based electronic health record from the Clinical Data Analysis and Reporting System (CDARS) in Hong Kong between 2014 and 2023 were included. The probable psychiatric indication was defined as the diagnosis recorded within 6 months from the date of SGA initiation and was classified into four groups according to the ICD-9-CM categorization of Mental Disorders (290-319). Trends were examined using joinpoint analyses. The prescription trend was re-analyzed using an alternative classification into groups of Schizophrenia (SCZ), Non-schizophrenia serious mental illness (non-SCZ SMI), and Non-SMI.

Results: A total of 79,681 patients (Female 57.9%, Age 56.8 ±22.5years) were included. There is significant increase in SGA prescriptions in patients with a probable indication within the ICD-9-CM category of 'Non-psychotic Mental Disorders' and 'Organic Psychotic Conditions', with an average annual percent change (AAPC) of 1.9% (p<0.01) and 1.7% (p<0.01), respectively; while the probable indications under 'Other Psychoses' decreased with an AAPC of -2.2% (p<0.01) (Figure 1). Importantly, the prescriptions among patients with probable diagnostic indications under the group of SCZ and non-SCZ SMI decreased with an AAPC of -6.9% (p<0.01) and -0.8% (p=0.03), respectively, while the non-SMI indications rose from 60.3% to 70.0% from 2014-2023 (AAPC=1.7%, p<0.01) (Figure 2).

Image 1:



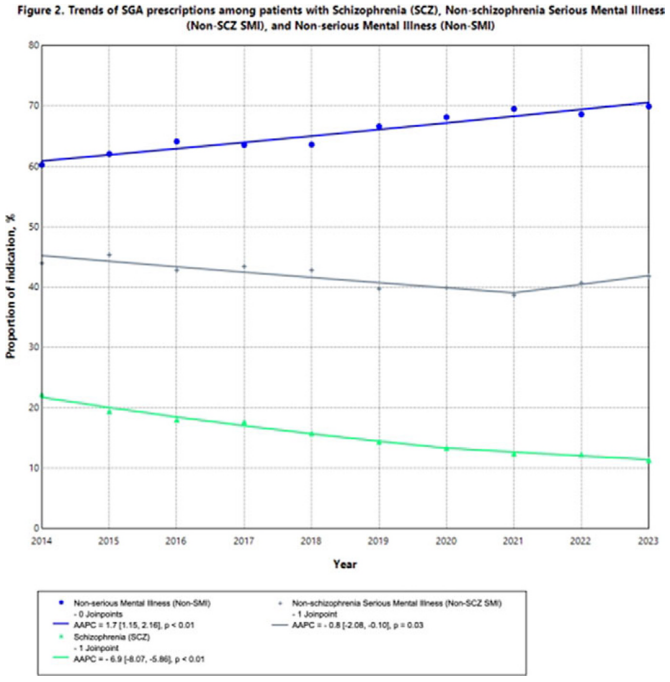


Image 2:

Conclusions: Our study provided important data demonstrating a trend of increasing proportions of SGA prescriptions for non-psychotic and non-SMI indications.

An analysis of spontaneous adverse drug reaction reports of psychiatric patients stratified by reporter type provides differentiated data

D. Dubrall[1,2]*, P. Christ[2], M. Schmid[1], B. Sachs[2,3] and C. Scholl[2]

[1]University Hospital Bonn; [2]Federal Institute for Drugs and Medical Devices, Bonn and [3]University Hospital RWTH Aachen, Aachen, Germany

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.553

Introduction: In Germany, psychiatric drugs are one of the most frequently prescribed drug class with more than two billion defined daily doses. As a consequence, a high number of patients carries a potential risk to develop an adverse drug reaction (ADR) to these drugs. It is known that spontaneous ADR reports from physicians, pharmacists and consumers differ regarding the drugs reported as suspected and the ADRs most frequently described. Most of the studies investigating differences in ADR reports from different reporter types are based on datasets without stratification into specific drug classes.

Objectives: The aim of our study was to analyse whether the reported psychiatric drugs, ADRs and types of psychiatric patients with regard to their psychiatric history and diagnosis differed between spontaneous ADR reports related to psychiatric drugs submitted by physicians, pharmacists and consumers.

Methods: Overall, we analysed 2,606 spontaneous ADR reports from physicians, 1,222 from pharmacists and 4,218 from consumers from Germany received for adults in which antidepressants, antipsychotics and mood stabilizers were reported as suspected/interacting. Comparative analyses between the ADR reports of the three reporter types concerning the psychiatric drugs reported as suspected/interacting, the histories of the patients and the reported ADRs were performed. Odds ratios (OR) with their 95% confidence intervals (CI) were calculated by a two-by-two table design.

Results: Consumers more commonly reported ADRs related to the drug classes of other antidepressants compared to pharmacists and physicians. In contrast, physicians reported ADRs occurring after the use of other antipsychotics more frequently compared to the respective other reporter types. Concerning the ADRs, sexual dysfunctions were more commonly described in ADR reports from consumers, laboratory investigations and their results more often in ADR reports from physicians and product quality issues in ADR reports from pharmacists. With regard to the psychiatric histories of the patients, ADR reports from consumers more often contained patients with anxiety disorders and ADR reports from physicians patients with schizophrenia and bipolar disorders.

Conclusions: Our study underlines the value of considering the ADR reports from the three different reporter types as these reports complement each other. This approach provides a more complete analysis of the drug safety and may therefore allow risk minimization measures, which integrate and specifically consider the perspectives of the respective reporter types if necessary.

Paliperidone Palmitate Long-Acting Injection in Schizophrenic Patients: Improved of Negative Symtons and Metabolic Rates. 6 Years of follow up

E. S. GISBERT

PSYCHIATRY, HOSPITAL UNIVERSITARIO INFANTA SOFIA, SAN SEBASTIAN DE LOS REYES, Spain

doi: 10.1192/j.eurpsy.2025.554

Introduction: PALIPERIDONE PALMITATE can improved the metabolic rates better than oral paliperidone. The negative symtoms and metabolic syndrome are a very frecuent phemomena with hard treatment.

Objectives: Find the differences in the improving of negative symtoms and the metabolic rates in patients with change of neuroleptic (oral to paliperidone palmitate injection).

Methods: MATERIAL AND METHODS: Observational longitudinal study during 72 months. We incluided all the patients with the diagnosis of schizophrenia, in which we done a change from oral neurolepic to Palmitate of Paliperidone and age of 18 years o more. There was a control group with paliperidone oral.

We used SANSS and CGI-Scale for negative symtoms and metabolic rates (weight, IMC, Glucose, Colestherol, TG and prolactin) and abdominal perimeter.

Results: 40 patients was included and only 4 refused. 56% are male. Average age 41.22 years. 24% has metabolic disease, 29% with axis IV disease and 30% with toxic substances Average dosis of palmate of paliperidone 105 mg/28 days.

The reason of change to injection was: No response 38% to oral neuroleptic treatment and side effects 28%. Rest patients wish.

Metabolic rates improved: Less in weight, IMC, Glucose, Colestherol, TG and prolactin and abdominal perimeter. These improved in the 6 years of study

The SANSS scale improved, All of them were stadistical significative ($p<0,05$) and CGI scale results improved.

Conclusions: CONCLUSIONS The change from oral neuroleptic to palmitate of paliperidone improved metabolic rates and abdominal perimeter.

Also improved SANSS and CGI Scale.

The palmitate of paliperidone is useful in schizophrenic patients and with less incidence of metabolic side efects and improved of negative symptoms.

New therapeutic option for treatment-resistant depression using transcranial pulse stimulation: real-world data from a case series

A. R. Günes[1]*, M. Beglau[1], M. Köhne[2] and U. Sprick[1]

[1]Center of Neurostimulation and [2]Alexius/ Josef Clinic, Neuss, Germany

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.555

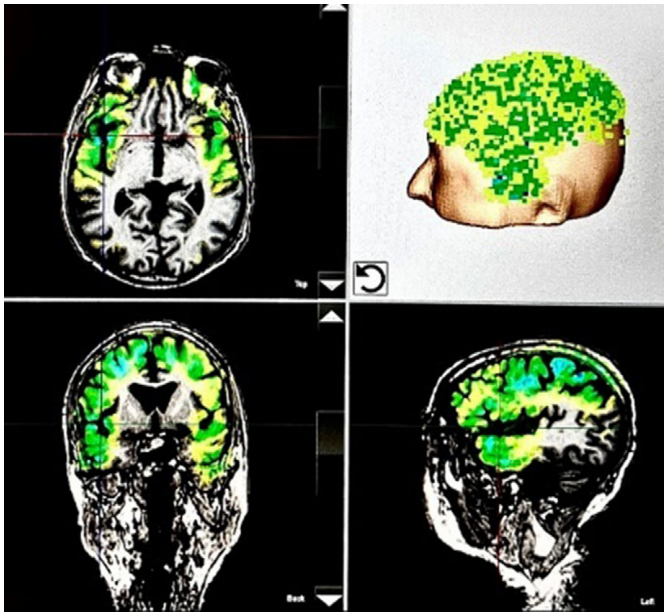
Introduction: As a result of crises such as the Covid-19 pandemic, depressive symptoms are increasing in the European population (Arias-de la Torre *et al.* Lancet PH 2023; 8: e889-98), with depression being one of the most common illnesses anyway and are even at the highest level ever measured in some countries, like in Germany (Mauz *et al.* Front PH 2023; 11: 106). Various treatment options are available, depending on the severity and individual preference of patients, but treatment-resistant depression in particular can pose major challenges for patients and clinicians. Transcranial pulse stimulation (TPS), an alternative NIBS method based on shock waves, has been available for several years and is CE-certified for the treatment of Alzheimer's dementia (Chen *et al.* CNS Nsc 2023; 00:1-10). It enables, for the first time, a precise and non-invasive modulation of subcortical brain regions where previously surgical intervention was necessary (Legon *et al.* Hum. Brain Mapp 2018; 39:1995-2006).

Objectives: The aim of this case series is to examine safety and effectiveness of TPS in patients with treatment-resistant depression.

Methods: In the present study, 5 patients (gender ratio female/male 3:2) who met the criteria for treatment-resistant depression underwent a total of 6 treatments within 14 days (each session with 6000 pulses, energy level 0.25 mJ/mm² and frequency 4 Hz). With the help of neuro-navigation using individual MRI scans, pulses were applied bilaterally in the frontal and parietal lobe as well as the precuneus area (Figure 1). Additionally the shell region of the nucleus accumbens was targeted with 300 pulses on both sides due to its involvement in the pathophysiology of depression. Written consent and the approval of an ethics committee were obtained for all patients. Before, during and immediately after the TPS intervention, the antidepressant medication of all patients remained unchanged. The Beck Depression Inventory (BDI-II) was used to assess the severity of depressive symptoms before the first and after the last treatment session.

Results: Apart from a temporary feeling of pressure in the area of the temples in one patient, none of the patients experienced any side effects during and after the treatment. All patients showed a reduction in the BDI-II total score in the pre-post comparison: the mean value decreased from 41 to 26 (Figure 2).

Image 1:



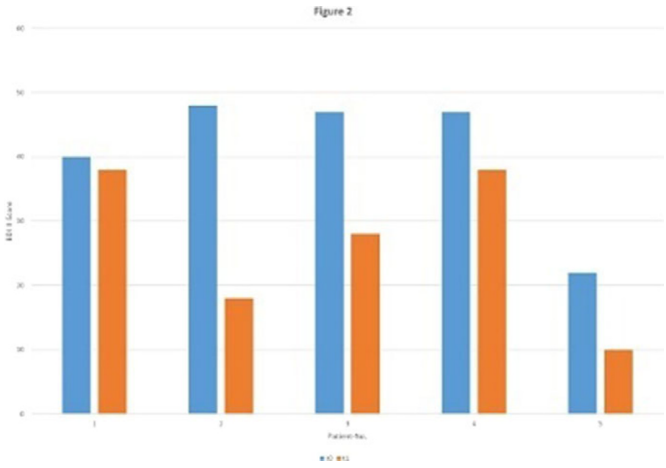


Image 2:

Conclusions: The results of this case series show that a significant improvement in depressive symptoms is possible using TPS as a potentially well-tolerated treatment option, even in cases of treatment-resistant depression. Sham-controlled studies with large numbers of patients are required to prove its long-term effectiveness and safety.

EPP243

Risk of cognitive disorders and cardio-cerebrovascular diseases after electroconvulsive therapy in patients with affective and psychotic disorders

H.-C. Kim

Psychiatry and Brain Research Institute, Keimyung University School of Medicine, Daegu, Korea, Republic Of
doi: 10.1192/j.eurpsy.2025.556

Introduction: Although electroconvulsive therapy (ECT) is one of the most important treatments for major mental disorders, many patients are concerned about the risk of developing cognitive impairment or cardio-cerebrovascular disease after ECT.
Objectives: This study aimed to compare the incidence of cognitive disorders and cardio-cerebrovascular diseases in the ECT group and the control group at a university hospital.
Methods: The subjects of this study were the ECT group (n = 173 people) who received ECT in patients with major affective or psychotic disorders, and the control group (n = 11,444 people) who did not receive ECT. The ECT and control groups were matched for demographic and clinical characteristics in a 1:5 ratio. This study investigated the incidence of cognitive disorders and cardio-cerebrovascular diseases through retrospective follow-up for up to 5 years after ECT. Statistical analysis used a multivariate Cox proportional hazards model to obtain the hazard ratio (HR) and 95% confidence interval (CI).
Results: The incidence rates per 1,000 patient-years in the ECT vs. control groups were 17.56 vs. 6.25 for cognitive disorders, 4.41 vs. 4.35 for cardiovascular diseases, and 2.28 vs. 2.48 for cerebrovascular diseases. The ECT group tended to have a higher incidence of cognitive disorders compared to the control group, but this was not statistically significant (HR, 2.46; 95% CI, 0.89–6.36; p=0.07). There was no significant difference in the risk of cardiovascular disease (HR, 1.50; 95% CI, 0.21–7.09; p=0.65) or cerebrovascular disease (HR, 0.96; 95% CI, 0.05–6.56; p=0.97) between the two groups.
Conclusions: This study showed that there were no significant differences in the incidence of cognitive disorders and cardio-cerebrovascular diseases between patients with major affective or psychotic disorders who received ECT and those who did not. This study suggests that ECT is a safe treatment, but further prospective multicenter collaborative follow-up studies are required to confirm this.

Transdiagnostic Effectiveness of Repetitive Transcranial Magnetic Stimulation for Mood and Anxiety Disorders

A. V. Samokhvalov[1,2,3,4]* and A. Doomra[1]

[1]Homewood Health Centre, Guelph; [2]Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton; [3]Dr. Sam's Health, Inc. and [4]Homewood Research Institute, Guelph, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.557

Introduction: Repetitive Transcranial Magnetic Stimulation (rTMS) is a novel neuromodulation treatment investigated for multiple psychiatric conditions and approved primarily for treatment-resistant depression (TRD) [1, 2]. There is a perceived potential for other clinical conditions, primarily other mood and anxiety disorders [2]. We have been using rTMS for treatment of patients with TRD of mixed etiology and multiple comorbidities.
Objectives: To evaluate the effectiveness and feasibility of rTMS in complex clinical populations.
Methods: Observational study. Quick Inventory of Depressive Symptomatology (QIDS). Generalized Anxiety Disorder Questionnaire (GAD-7). Descriptive statistics.
Results: We have treated 90 patients, 46 women (51.1%) and 44 men (48.9%), with average age of 42.5±16.9 years. Vast majority (88.9%) of patients had a primary diagnosis of major depressive disorder, 8.9% had bipolar depression, and two patients had primary anxiety disorders. The standard questionnaires were used to quantify the severity of depressive symptoms (QIDS) and anxiety (GAD-7). The average baseline scores for depression and anxiety were 16.6±4.9 and 12.7±5.5, respectively. The patients received an average of 24.0±7.0 treatments. Almost all patients received the full course of 20-30 treatments as planned. The average end-of-treatment (EoT) scores for severity of depressive symptoms and anxiety were 10.5±6.1 and 8.4±5.8, respectively. The rates of improvement and complete resolution of depressive symptoms were 64.4% and 28.7%, respectively. The rates of improvement and complete resolution of anxiety symptoms were 53.5% and 29.6%, respectively. There was a significant difference between the bipolar and major depression in terms of baseline depressive symptoms severity and improvement rates, but there was no difference in respect to anxiety symptoms (see Figure 1).

Image 1:

Conclusions: rTMS provides significant improvement and recovery rates in complex clinical populations and is well-tolerated. We recommend wider implementation of rTMS for treatment of mood and anxiety disorders.

EPP245

Neuronavigated Transcranial Pulse Stimulation (TPS) with shock waves as a novel tool of noninvasive brainstimulation (NIB) for a long-term treatment of Alzheimer's disease

U. Sprick[1]*, A. R. Günes[1], M. V. Beglau[1] and M. Köhne[2]
[1]Center of Neurostimulation and [2]Alexius/Josef Clinic, Neuss, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.558

Introduction: Alzheimer's disease (AD) is a very common cause of dementia and a common cause of death in elderly humans. No effective long-term treatment has been found so far. Recently developed treatments with antibodies have shown severe side effects of edema or intracerebral hemorrhage in a larger number of cases.
Objectives: Neuronavigated transcranial pulse stimulation (TPS) as a new non-invasive therapy method could represent a current alternative to standard treatments. In contrast to ultrasound stimulation (tFUS) TPS uses shock waves with a mechanical transduction. These shock waves allow an application to superficial brain structures as well as into areas deep in the brain without the induction of any unwanted thermal side effects. The stimulation of the target areas can be MRI-navigated with nearly a similar precision as in stereotactical procedures.
Methods: 85 out-patients with Alzheimer's disease with light to moderate symptoms received TPS-treatments with 6.000 pulses each session bilaterally in 6 sessions over 2 weeks into the frontal, parietal and temporal cortex (0.2 mJ/mm^2 4 Hz - Neurolith by Storz Medical). The treatment was repeated with a single booster session every 6 weeks. Pulses were inividually neuronavigated by current MRI-images. Executive functions were tested using the Stroop-Test (colour-word-interference-test). Patients with Alzheimer's Disease normaly present only poor results in the Stroop-Test. We tested with a pre – post design (t_0 pre stimulation : t_1 after 6 sessions, two weeks later as well as t_2 6 months later). The mood of the patients was measured using the BDI on t_0, t_1 and t_2.
Results: TPS-stimulation showed strong ameliorating effects on performance in the Stroop-Test. The mean-score of the Stroop-test was diminished significantly (pre vs. post ; $p < 0.05$ – paired T-test) in a comparison of t_0 to t_1. This effect was preserved during an interval of 6 months (t_2). Single patients showed extraordinary improvements by shortening completer times in the Stroop-Test by half.
Depressive symptoms of the patients were also diminished by the treatment. The BDI score decreased from 20.1 (t_0) to 9.7 (t_1), and 9,1 (t_2) respectively.
No significant side-effects occured during all the sessions in any of the patients.
Conclusions: The results of this trial show that cognitive impairments of executive functions and depressive symptoms in Alzheimer's disease may be ameliorated using TPS as a noninvasive neuronavigated brain stimulation method. No severe side-effects were observed. In the meantime beneficial effects of shockwaves with low intensitiy have also been shown in the fields of dermatology, orthopedics and cardial surgery.
Different mechanisms of action of TPS are still under investigation.

EPP248

The Relationship Between Sensory Processing and Executive Functions in Adults with and without Neurodevelopmental Disorders

S. Regev[1], K. Sharfi[1]*, O. Cohen Elimelech[2], N. Grinblat[2] and S. Rosenblum[2]
[1]Occupational Therapy, Ben-Gurion University of the Negev, Beer-Sheva and [2]Occupational Therapy, University of Haifa, Haifa, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.560

Introduction: Existing literature highlights unique sensory processing patterns and decreased executive functions (EF) in adults with neurodevelopmental disorders (NDD). However, most studies have focused on specific diagnoses, such as Attention-Deficit Hyperactivity Disorder or Specific Learning Disabilities, and have used smaller sample sizes, indicating a need for broader and more comprehensive research.
Objectives: Based on prior research conducted in the same laboratory, the current study aimed to comprehensively evaluate sensory processing patterns and EF in adults with NDD compared to controls, as well as to explore the relationships between these characteristics within each group.
Methods: The study sample included 290 adults (aged 20–50 years), comprising 149 individuals with NDD and 141 matched controls. Participants completed the Adolescent/Adult Sensory Profile (AASP) and the Adult Behavior Rating Inventory of Executive Function (BRIEF).
Results: Significant group differences were found in the AASP scores ($F(4,285) = 42.05$, $p < .001$, $\eta p^2 = 0.37$), with variations in three sensory processing subscales: low registration ($F(1,288) = 149.92$, $p < .001$, $\eta p^2 = 0.34$), sensitivity ($F(1,288) = 103.97$, $p < .001$, $\eta p^2 = 0.26$), and avoidance ($F(1,288) = 50.06$, $p < .001$, $\eta p^2 = 0.48$), though not in sensory seeking. Additionally, significant differences were observed in the BRIEF ($F(5,284) = 67.58$, $p < .001$) across all nine subscales and indexes. Notably, significant correlations were identified between BRIEF scores and three AASP subscales in both groups: low registration (control: $r = .50$, $p < .001$;

NDD: r = .54, p < .001), sensitivity (control: r = .45, p < .001; NDD: r = .47, p < .001), and avoidance (control: r = .45, p < .001; NDD: r = .42, p < .001).
Conclusions: This study highlights the distinct sensory processing patterns and EF challenges in adults with NDD compared to controls. The findings also reveal a consistent relationship between sensory processing and EF across both groups. These insights enhance the understanding of the interplay between sensory and executive functioning, emphasizing the importance of considering these characteristics at assessment and intervention of adults with NDD.

Key Components of Cognitive Remediation for Schizophrenia: A Bayesian Network Meta-Analysis

L. Van Der Meer[1,2]*, T. Brands[3], T. van Brouwershaven[2], M. L. Thomas[4], N. Buist[1,2], E. Twamley[5,6], A. Vita[7], G. H. Pijnenborg[1,8] and A. Poppe[1,9]

[1]Clinical & Developmental neuropsychology, University of Groningen, Groningen; [2]Department of Rehabilitation, Lentis Psychiatric Institute, Zuidlaren, Netherlands; [3]LVR Viersen, Viersen, Germany; [4]Department of Psychology, Colorado State University, Fort Collins; [5]Department of Psychiatry, University of California San Diego; [6]Center of Excellence for Stress and Mental Health, VA San Diego Healthcare System, San Diego, United States; [7]Department of Clinical and Experimental Sciences, University of Brescia, Brescia, Italy; [8]Department of Psychotic Disorders, GGZ Drenthe, Assen and [9]Radboud university, Nijmegen, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.561

Introduction: Cognitive impairments are strongly associated with impaired everyday functioning in individuals with schizophrenia, and cognitive remediation (CR) has been identified as effective treatment. However, uncertainty remains regarding the most effective components of CR.
Objectives: To identify (1) the most effective combination of core ingredients of CR (cognitive exercises, presence of a therapist, cognitive strategies, and generalization activities) and (2) the most effective type of CR to improve everyday functioning in individuals with schizophrenia (computer-assisted cognitive remediation, single domain computer-assisted cognitive remediation, social cognition interventions, paper and pencil interventions, integrative approaches, and combination approaches).
Methods: PubMed, PsycInfo, Medline, Embase were searched literature from inception until November 25, 2022. Reference lists of included studies and previous meta-analyses were searched for relevant studies. We included randomized controlled trials comparing CR with any control condition or a different type of CR, assessing everyday functioning pre- and post-intervention in individuals with schizophrenia. The studies were selected independently by two reviewers. We followed the PRISMA guidelines. Study data were extracted independently by two reviewers. Data were analyzed using Bayesian random-effects network models. Trial methodological quality was evaluated with the Clinical Trials Assessment Measure. Risk of bias was evaluated. Primary outcomes were changes in functioning and cognition from baseline to after CR and from baseline to followup (min. 3 months). Literature search was updated in September 2024.
Results: 86 studies and 6076 participants were included. For both outcomes, the most effective constellation of core elements of CR were cognitive exercises, CR provided by a therapist and the use of generalization procedures (functioning: g = 0.31, 95% CrI [0.14, 0.47]; cognition: g = -0.23, 95% CrI [0.03, 0.42]). Moreover, only combinations that included both cognitive exercises and a therapist were more effective than TAU. All four core elements were necessary to observe improved functioning at follow-up. For the specific types of CR, none was superior to any other CR type. All CR types were more effective in improving functioning compared to TAU (g = 0.19-0.45). Study quality did not influence the results. Results will be updated if necessary after inclusion of the updated literature search.
Conclusions: The findings indicate that the effectiveness of CR depends on the inclusion of four essential elements—cognitive exercises, therapist involvement, strategies, and generalization activities—rather than on the specific type of CR intervention. An update to the definition of CR is recommended.

The Family Mental Health Cafés: A psychoeducation intervention to diminish stigma and isolation for families living with mental illness

C. C. Williams[1,2]

[1]Factor-Inwentash Faculty of Social work and [2]Rehabilitation Sciences Institute, Temerty Faculty of Medicine, University of Toronto, Toronto, Canada
doi: 10.1192/j.eurpsy.2025.562

Introduction: Psychoeducation is a well-supported intervention in psychiatry aimed at improving outcomes for patients with serious mental disorders and their families. It primarily focuses on enhancing family understanding of the illness, reducing stress, and fostering a supportive environment for the patient. However, traditional psychoeducation often emphasizes increasing caregivers' capacity to manage the illness, rather than addressing the family as a unit coping with care needs and the stigma associated with mental illness. Family mental health cafés have been developed to address these broader issues.
Objectives: The aim of this study was to explore the experiences of participants in family mental health cafés and evaluate its impact on feelings of stigma and isolation.
Methods: The Family Mental Health Cafés were implemented in five Ontario cities from 2018 to 2019, these cafés were organized in collaboration with the Canadian Mental Health Association. They drew on the World Café and Death Café models, focusing on caregiving and care-receiving within the family unit and its interactions with the community. Discussions included managing illness and other stressors, successful strategies, and improvements needed for family well-being. Participants completed evaluations with both closed and open-ended questions
Results: A total of 67 individuals participated, identifying as diagnosed individuals, family members, service providers, or combinations thereof. Sixty-six completed evaluations, with 99% finding the cafés well-planned and engaging, and 88% recommending them to others. Qualitative feedback emphasized the value of shared

experiences, resource exchange, and diverse perspectives from patients, family members, and service providers. Participants appreciated the integration of these perspectives as a positive aspect of the café experience.
Conclusions: The cafés offer a novel approach to psychoeducation by focusing on the well-being of the entire family, their mutual caregiving investments, and challenges in navigating social and institutional environments. Participants valued the process for addressing isolation, and engagement with others with similar experiences may have helped reduce stigma, though this was less clear. Future research could explore the long-term outcomes of single or repeated café experiences.

Cariprazine & clozapine: A systematic review of a promising combination in the management of treatment-resistant schizophrenia

S. Pappa[1,2], Z. B. Dombi[3], E. Caldwell-Dunn[2], R. Csehi[3]* and Á. Barabássy[3]
[1]Imperial College London; [2]West London NHS Trust, London, United Kingdom and [3]Gedeon Richter Plc., Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.563

Introduction: Up to 30-70% of patients with treatment-resistant schizophrenia (TRS) remain symptomatic despite gold standard treatment, clozapine. To date, commonly used antipsychotics have demonstrated little therapeutic benefit as augmenting agents in comparison to placebo. Emerging evidence suggests that novel D2-D3 partial agonist cariprazine is a promising augmentation strategy to clozapine for TRS.
Objectives: This systematic review aims to collect the available real-world evidence of effectiveness and tolerability of cariprazine and clozapine combination treatment.
Methods: A systematic review was performed using PubMed, MEDLINE, EMBASE and Cochrane databases from January 2017 until September 2024 for cases where cariprazine was used as an augmentation strategy for clozapine with the following terms: (cariprazin*) AND (clozapin*) AND ('case report*' OR 'case report'/de OR 'case stud*' OR 'case study'/de OR 'case seri*' OR 'add-on' OR augmentation OR combin*).
Results: After removal of duplicates, 108 studies were retrieved, of which 20 studies were included (one prospective pilot study and 19 case reports). Total cases comprised of 47 patients (30 male, 17 female), with diagnoses of schizophrenia (n=40), schizoaffective disorder (n=6) and emotionally unstable personality disorder (EUPD) and autism spectrum disorder (n=1). Patients were treated with clozapine (dose range 37.5-850 mg/day) and cariprazine (doses 1.5-6.0 mg/day) for a median of 122 days (range 18-456). Although a variety of subjective and objective outcome measures were employed, cariprazine was generally found to be a well-tolerated and effective adjunct to clozapine in a wide range of different symptom profiles; demonstrating efficacy across positive, negative and affective symptoms, quality of life and global functioning in the majority of cases. Additional benefits of weight loss and improving commonly experienced adverse side effects of clozapine were also frequently reported. In 3 cases cariprazine augmentation did not improve symptomatology, whereas in 6 cases the combination resulted in the exacerbation of different symptoms such as anxiety or restlessness.
Conclusions: By targeting different receptors, cariprazine and clozapine appear to act synergistically allowing for a well-tolerated and effective antipsychotic combination. Large-scale RCTs are warranted to further evaluate its effectiveness compared to placebo.

Predominant negative symptoms in female schizophrenia in-patients: An observational study

J. Dragasek[1], Z. B. Dombi[2]*, P. Herman[2], V. Dzurilla[3] and Á. Barabássy[2]
[1]University of P. J. Safarik, Kosice, Slovakia; [2]Gedeon Richter Plc., Budapest, Hungary and [3]Gedeon Richter Slovakia, Bratislava, Slovakia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.564

Introduction: Negative symptoms are a key aspect of schizophrenia, significantly impacting a patient's functioning and quality of life. Although hospitalizations are often associated with positive symptoms, negative symptoms can also dominate the clinical picture in in-patients. Female patients are usually underrepresented in schizophrenia studies.
Objectives: To analyse the changes of negative symptoms in female in-patients.
Methods: This was an observational study with data recorded at hospital entry and release. Adult inpatients with a schizophrenia diagnosis according to the International Classification of Diseases 10th edition who exhibited predominant negative symptoms according to clinical judgement were included. Patients received pharmacological and some non-pharmacological treatment as usual.
The primary outcome measure was the modified Short Assessment of Negative Domains (m-SAND), an anamnesis-based scale that is composed of 7 items: two positive items (delusions and hallucinations) and five negative items (anhedonia, alogia, avolition, asociality and affective flattening). Each item is rated from 0 to 5 (not observed; mild; moderate; moderately severe; severe; and extreme). Other measurements included the Self-evaluation of Negative Symptoms (SNS).
Least squares (LS) means were calculated for the change from baseline to final visit using a mixed model for repeated measures (MMRM).
Results: 63 female patients were included in the study. The mean age was 41.6 years with 14.2 years of mean duration of illness. All patients had predominant negative symptoms, in fact, 65% of them was hospitalized because of it. 30% of the patients also had secondary negative symptoms, mainly due to positive symptoms. The mean duration of hospital stay was 38 days. All patients received pharmacotherapy. At baseline, 9.5% were on cariprazine monotherapy and 84.1% on cariprazine combined with another

antipsychotic such as olanzapine (23.8%) or quetiapine (7.9%). By the end of the hospital stay, 14.3% of female patients received cariprazine monotherapy and 82.5% cariprazine combination treatment with olanzapine (30.2%) or clozapine (15.9%). Significant decrease was detected in m-SNAD total score (LS mean change from baseline: -10.95) and SNS total score (LS mean change from baseline: -9.74). Functioning increased from poor (76%) to 'manifest disabilities' according to PSP (81%).
Conclusions: In summary, female patients had significant improvement during their hospital stay in terms of negative symptoms. The most utilized pharmacotherapy during the hospital stay was cariprazine both in a form of mono- and polytherapy.

Relapse prevention with cariprazine: A focus on sex

C. Correll[1], Z. B. Dombi[2]*, P. Herman[2] and Á. Barabássy[2]

[1]The Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, NY, United States and [2]Gedeon Richter Plc., Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.565

Introduction: Relapse refers to the recurrence of psychotic symptoms following a phase of improvement or stability. It often leads to the disruptive re-hospitalization of patients. Notably, a history of relapse is a strong indicator of future relapses and poorer outcomes. According to the literature, relapse rates might be higher in men compared to women due to better response to medication in women. Cariprazine (CAR), a D3-D2 partial agonist, has shown effectiveness in preventing relapse compared to a placebo in stabilized schizophrenia patients
Objectives: We aimed to investigate whether there is a difference in the efficacy of CAR in preventing relapse by sex.
Methods: A post-hoc analysis was conducted on data from a multicentre, randomized, double-blind, placebo-controlled, parallel-group study lasting approximately 96 weeks in adults with schizophrenia. The study included two phases: a 20-week open-label treatment phase and a double-blind treatment phase lasting up to 72 weeks. During the open-label phase, patients were stabilized on CAR at doses of 3.0-9.0 mg/day. Subsequently, they were randomized to either continue CAR (at fixed doses of 3.0, 6.0, or 9.0 mg/day) or switch to a placebo (PBO). Relapse was defined by a worsening of symptom scores on the Positive and Negative Syndrome Scale (PANSS), psychiatric hospital admission, aggressive behaviour, or suicide risk. In this analysis, patients were separately analysed based on their sex. Baseline characteristics, hazard ratios by sex during the double-blind phase were calculated.
Results: Of 200 patients, 132 (66%) were male (M) and 68 (34%) were female (F). In the female group, 57% were receiving CAR treatment, while in the male group 47% were on CAR. The mean age of the patients was between 36-41 years. The open-label baseline PANSS scores were comparable. The adherence of patients during the double-label phase was similar in all four groups (98-99%).
More relapses were documented in the placebo groups (M: 47%, F: 48%) than in the CAR groups (M: 27%, F: 21%). In females, those who received CAR during the double-blind phase had 66% less risk for relapse (HR=0.34, 95%CI= 0.14-0.82) than those who were on placebo. Similarly, male patients on cariprazine had 49% less risk for relapse (HR=0.51, 95%CI= 0.28-0.91) than those receiving placebo. The Cox regression analysis between groups showed that sex of patients did not affect the risk of relapse significantly.
Conclusions: In summary, sex does not seem to significantly influence risk of relapse. CAR decreases the risk of relapse compared to placebo in both males and females.

Functional Recovery Levels, Associated Clinical Features and the Role of Metabolic Syndrome in Schizophrenia Patients Followed in a University Hospital

G. Şimşek Avcı

psychiatry, Gazi university hospital, ankara, Türkiye
doi: 10.1192/j.eurpsy.2025.566

Introduction: Schizophrenia is a chronic illness that causes severe disability and dysfunction.The traditional approach focusing on symptom control does not always result in improvement in functioning. Functional recovery is considered to be the achievement of social and occupational functioning and independent living in addition to symptom remission.Factors like negative symptoms, depression, cognitive dysfunction, treatment compliance, internalised stigma, and education impact functional recovery. MetS may impact functional recovery by contributing to depression, reducing treatment compliance, and impairing cognitive functions, but studies on this are limited.
Objectives: This study aimed to investigate the relationship between MetS and functional recovery in schizophrenia, along with related clinical features.
Methods: The study sample included 115 schizophrenia patients aged 18-65, who applied to Gazi University Psychiatry Outpatient Clinic, spoke Turkish, no exacerbation in the last year.Exclusion criteria were serious medical/neurological illness, alcohol/substance use disorder.MetS was diagnosed per American College of Cardiology criteria. Functional Remission of General Schzophrenia Scale (FROGS), Schizophrenia Cognition Rating Scale (SCoRS), Positive and Negative Syndrome Scale (PANSS), The Calgary Depression Scale for Schizophrenia (CDSS), Medication Adherence Rating Scale (MARS), Schedule for Assesing the Three Components of Insight (SAI), Internalized Stigma of Mental Illness Scale (ISMI) scales were applied to all participants. SPSS 22.0 was used, and $p<0.05$ was considered significant.
Results: The mean age of participants was 48.61, 54.8% were male and 44% had a high school education. MetS was 55.7% of patients. Patients with MetS had significantly lower scores of FROGS,

showed more cognitive impairment in problem solving, there were no significant differences between the groups in the other variables examined.The proportion of patients with MetS (79.7%) showing low level of functionality was higher than those without MetS.The total score of FROGS was positively correlated with years of education, scores of MARS and SAI, while it was negatively correlated with age and CDSS scores.Among the components of MetS, fasting glucose level and diastolic blood pressure were found to be significantly correlated with the scores of the FROGS.The negative predictors of functioning were found to be education level, MARS scores, MetS, SCoRS attention domain and PANSS negative scores.
Conclusions: Our results show that MetS associated with lower functionality in schizophrenia. Therefore, good metabolic control in patients with schizophrenia is important for cognitive skills and functionality as well as physical health.

Effects of DORA Daridorexant on insomnia disorder in patients with comorbid unipolar and bipolar depression: data from a naturalistic longitudinal study

L. Anastasio[1]*, G. Alfi[2], G. Aquino[2], E. Annuzzi[1], G. Cerofolini[1], A. Coccoglioniti[1], M. Gambini[1], M. Pioltino[1], G. Perugi[1], A. Gemignani[1] and L. Palagini[1]

[1]Department of Neuroscience, Psychiatric Unit, Azienda Ospedaliera Universitaria Pisana (AUOP), University ofPisa, Pisa, Italy and [2]University of Pisa, Pisa, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.567

Introduction: Insomnia is the most *common* sleep disorder, which may *favor*, precipitate, and prolong mental disturbances, including mood disorders. *The treatment of* insomnia in the context of mood disorders may contribute to *improving* their trajectories, *possibly by* improving mood symptoms via sleep regulation. Daridorexant is a new *pharmacological option for insomnia treatment,* which is a *dual orexin receptor antagonist (DORA).*
Objectives: The aim of the present study was to treat consecutive patients with insomnia disorder with and without mental comorbidities with this new therapeutic option.
Methods: Ninety consecutive patients with insomnia disorder according to the DSM-5-TR criteria were treated with daridorexant 50 mg. Baseline, 1 month, and 3-month evaluations were performed. Demographic and clinical data were incorporated. Insomnia severity (Insomnia Severity Index-ISI), mood symptoms (Beck Depression Inventory II-BDI-II, Young Mania Rating Scale-YMRS), suicidal ideation (Suicidal Ideation Scale-SSI), and emotional dysregulation (Difficulties in Emotion Regulation Scale-DERS) were evaluated. The evaluation of psychiatric diagnosis was conducted in accordance with the DSM-5-TR criteria (SCID-5) and the concurrent use of pharmacological therapy was taken into account.
Results: The final sample included 80 patients (N° 40, 50.0% females, mean age 60 ± 13.2). Most of them (N°50 62.5%) suffered from insomnia comorbid with unipolar/bipolar depression. Repeated Anova analyses showed that ISI and DERS total score decreased across time (respectively $F=63.42$, $p<0.001$, $F=41.12$, $p<0.001$). Similarly depressive and mixed symptoms, suicidal ideation and anxiety symptoms significantly improved over time and after 3 months of treatment (respectively $F=62.45$, $p<0.001$, $F=31.48$, $p<0.001$, $F=41.14$, $p<0.001$, $F=21.44$, $p<0.001$). Analyses conducted on a subsample of patients with comorbid unipolar and bipolar disorder revealed a distinct beneficial effect on insomnia and mood symptoms. Multiple regression models demonstrated that improvement of depressive symptoms was best predicted by the improvement in emotion regulation -DERS score at T1 and T2, and the improvement in insomnia symptoms at T1. An improvement in manic symptoms-YMRS score was best predicted by an improvement in insomnia symptoms-ISI score and in emotion regulation at T1 and T2.
Conclusions: The treatment of chronic insomnia with daridorexant improved insomnia symptoms in patients with and without mental comorbidities across time. It was particularly effective in patients with unipolar and bipolar disorders, where the improvement in mood symptoms was related to the improvement in insomnia across time. These data are in line with the data showing that targeting insomnia in the context of mood disorders might be useful for improving sleep and mood symptoms by regulating the sleep system.

Association Between Age and Sleep Quality: Findings From a Community Health Survey

J. Jeong[1]* and J. Hong[2]

[1]Psychiatry, St. Vincent's Hospital The Catholic University of Korea, Suwon and [2]Psychiatry, Iksan Hospital , Iksan, Korea, Republic Of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.568

Introduction: With increase in life expectancy, there is growing interest in quality of life. Sleep is receiving increasing attention among the elderly.
Objectives: This study aimed to investigate the changes in sleep quality with increasing age and the effect of age on the components of the Pittsburgh Sleep Quality Index (PSQI).
Methods: We used data from the Community Health Survey conducted by the Korea Center for Disease Control and Prevention in 2018. A total of 228340 participants in this nationwide survey. Sleep quality was assessed using the PSQI. Adults aged ≥ 19 years were divided into six age groups and one-way analysis of variance (one-way ANOVA) was used to compare the mean values of PSQI of each group. By comparing the scores for each PSQI component in those aged ≥ 65 years and < 65 years, we aimed to reveal the differences in special components according to age group.
Results: In total, 223334 respondents were included in the study. Based on a one-way ANOVA, the PSQI score generally increased with age. Although the average PSQI score of patients in their 40s was lower than that of patients in their 30s, there was no significant difference between the two groups ($p = 0.11$). When the PSQI

component was compared between the population aged over and under 65 years, the population aged ≥ 65 years scored higher in most components. In contrast, daytime dysfunction scored higher in the population aged < 65 years.
Conclusions: Sleep quality tends to decrease with increasing age. Several factors, including physiological changes, underlying physical conditions, and psychosocial factors, may contribute to a decrease in sleep quality with age.

Sleep Deprivation's Effect on Circadian Genes Expression and Its Associtations with Depression Symtoms and Psychomotor Abilities

A. Witkowska[1]*, A. Gabryelska[1], M. Ditmer[1], A. Tarasiuk-Zawadzka[2], A. Binienda[2], S. Turkiewicz[1], F. F. Karuga[1], P. Białasiewicz[1], J. Fichna[2] and M. Sochal[1]

[1]Department of Sleep Medicine and Metabolic Disorders and [2]Department of Biochemistry, Medical Univeristy of Lodz, Łódź, Poland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.570

Introduction: Sleep deprivation (SD) is a global health concern that impairs cognitive and psychomotor functions (PF). While it can temporarily improve mood, its effects on mood and connection to depressive symptoms (DS) remain unclear. These impacts may involve circadian rhythm gene regulation, though distinct evidence from human studies is lacking.
Objectives: To assess the impact of SD on the expression of circadian rhythm regulation genes and its associations with the alleviation of DS. Additionally, to explore the relationship between changes in gene expression and PF following SD.
Methods: Participants (n = 72) underwent a baseline sleep assessment by polysomnography (PSG), later being subjected to SD. In total, evaluation of mood And cognitive functions (Bimanual Eye-Hand Coordination Test - BEHCT) was conducted four times, pre/post PSG and SD. Moreover, circadian rhythm regulation genes expression: Circadian Locomotor Output Cycles Kaput (CLOCK), Brain and muscle Arnt-like protein-1 (BMAL1), Period Circadian Regulator 1 (PER1), Cryptochrome Circadian Regulator 1 (CRY1), Nuclear Receptor Subfamily 1 Group D Member 1 (NR1D1) and Neuronal PAS Domain Protein 2 (NPAS2) was evaluated. Participants were divided into respondents (RE, n = 49) and non-respondents (NR, n = 23) depending on changes in DS under the influence of SD by the Montgomery–Åsberg Depression Rating Scale evalluation.
Results: No relationship was found between BEHCT parameters and the studied genes in the entire study group. NRs exhibited a negative correlation in number of motor function errors in relation to all examined genes of CLOCK (r=-0.52, p=0.02), BMAL1 (r=-0.55, p=0.007), CRY1(r=-0.45, p=0.048), PER1(r=-0.6, p=0.023), and NR1D1 (r=-0.19, p=0.523) is except for NPAS2. Additionally, In NRs, the BEHCT error time negatively correlated with the PER1 and NR1D1 (r=-0.6, p=0.006; r=-0.52, p=0.045; respectively). In contrast, within the RE group, only NPAS2 expression showed a positive correlation with the number of errors (r= 0.35, p=0.049).
Conclusions: Reduced expression of CLOCK, BMAL1, CRY1, PER1, and NR1D1 is associated with impaired PF, only in individuals with worsening DS after SD. Increased NPAS2 expression appears to be an orgin of reduced PF results in the RE group. These genes, integral to the circadian system's feedback loop, may mediate the complex effects of SD on mood and cognitive function, warranting further investigation.

Perinatal depression and psychiatric comorbidities during the life course: a Swedish nationwide register based study

E. Bränn[1]*, D. Lu[1] and A. Duna[1]

[1]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.571

Introduction: Women with a history of major depression are at risk of perinatal depression (PND). The associations between PND and other types of psychiatric disorders are less clear, although a recent GWAS revealed genetic correlations with almost all psychiatric disorders.
Objectives: The aim of this study was to examine the association between PND and overall, and 17 type-specific, psychiatric disorders in a life course approach.
Methods: Leveraging Swedish nationwide health register and primary care data, we included all birthing women diagnosed with depression or prescribed for antidepressants during pregnancy or within a year postpartum, i.e., women with PND (n=122,720), during 2001-2022. Using incidence density sampling, we matched each case to 10 unaffected birthing women. We ascertained any diagnosis of psychiatric disorder over the lifetime from the National Patient Register. Using multivariable conditional logistic regressions, we estimated the association between PND and any, or subtypes of, psychiatric disorders dated before or after the PND diagnosis in a liftecourse approach. Moreover, we conducted a nested case control study to investigate the association of psychiatric disorders and subsequent PND, and a matched cohort study to investigate PND and subsequent psychiatric disorders.
Results: In preliminary results, at a mean age of 31.0, we found that PND was highly associated with any other psychiatric disorders (adjusted odds ratio (aOR)=9.02, 95%CI 8.9-9.2). The association remained when excluding depression (aOR=6.2, 95%CI 6.1-6.3), and was comparable for psychiatric disorders dated before PND diagnosis (aOR = 9.0), whereas attenuated for diagnoses dated after PND (OR= 3.9). Most pronounced association was noted for bipolar, personality disorders, depression, and anxiety. The association was stronger in primiparous women and in women born ourside of Europe (p-for interaction <0.001).
Conclusions: Throughout life course, PND is associated with psychiatric disorders, particularly with bipolar disorder, personality disorder, depression and anxiety. These findings may shed light on shared genetic/risk factors between PND and other psychiatric disorders.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.572

Introduction: Women generally have a later age of onset, and may therefore have a more favourable course of psychotic illness than men regarding psychopathology. Little is known about a broader range of outcomes, including well-being and recovery, and about the influence of age of onset.
Objectives: This study examines longitudinal sex-related and age of onset-related differences in well-being and recovery of people with a psychotic disorder with long illness durations.
Methods: Routine outcome monitoring data (2012-2021) of n=3843 patients were used. Well-being (quality of life and personal recovery) and recovery (clinical and societal recovery and psychosocial functioning) were assessed. Latent class growth analysis (LCGA) was performed to assess whether classes with different trajectories of well-being and recovery could be identified. Classes were related to sex and (early/late) age of onset of psychosis (EOP/LOP).
Results: LCGA identified five classes with varying combinations in levels of well-being and recovery, which were stable over time. Sex, age of onset and the combination of these two were significantly related to class membership. Women and individuals with LOP were more prevalent in better functioning classes than men and individuals with EOP.
Conclusions: This study showed sex differences in long-term recovery patterns of psychosis. Not only women but also individuals with LOP had a higher chance of better well-being and recovery, while men with EOP were at risk for worse outcomes. Taking these sex differences into account when deciding on policy and treatment protocols for individual patients might provide better mental health care to people with psychosis.

Association Between Premenstrual Disorders and Quality of Life: A Cross-Sectional Study of 8311 women in Sweden

Q. Wang[1*] and D. Lu[2]

[1]Karolinska Institutet, Stockholm, Sweden and [2]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.573

Introduction: Premenstrual disorders (PMDs), including premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD), manifest a range of affective, cognitive, behavioral, and physical symptoms during the late luteal phase of the menstrual cycle. Several studies have indicated that women with PMDs have a lower health-related quality of life, though findings on specific affected dimensions vary. Most of them relied on community- or clinical setting-based sampling, limiting the generalization. Furthermore, no prior study has formally assessed the association by accounting for the potential confounders. Therefore, we conducted a cross-sectional study based on the LifeGene cohort to evaluate the difference in quality of life among women with and without PMDs.
Objectives: We seek to understand, to what extent and in which way PMDs may impact the quality of life of women in Sweden.
Methods: We conducted a cross-sectional study of 8311 women enrolled to the LifeGene cohort during 2009-2019 in Sweden. PMDs were assessed with the modified Premenstrual Symptom Screening Tool at baseline, while data on quality of life (QoL) was obtained using the EQ-5D-3L scale (the higher the score, the worse the quality of life) from the LifeGene baseline dataset. Linear regression models were employed to assess the QoL score change associated with PMDs, as well as the separate analyses for PMDD and PMS. The models were adjusted for age, education level, country of birth, marital status, obesity, smoking, alcohol consumption, and childhood abuse.
Results: At a mean age of 34.01 years (SD=9.63), 1903 (22.90%) women met the criteria for PMDs. In the crude analysis, PMDs were positively associated with a lower quality of life (mean increased QoL score: 0.37, CI: 0.32-0.42). After adjustment for demographics and potential confounders, similar results were yielded (mean increased QoL score: 0.34, CI: 0.29-0.39). Among the five indicators included in the questionnaire (mobility, self-care, activity, pain and anxiety), only self-care was not associated with PMDs. For PMD subtypes, we found a lower quality of life among women with PMDD (mean increased QoL score: 0.35, CI: 0.30-0.41) but not among women with PMS.
Conclusions: Our findings suggested that women with PMDD had a lower quality of life compared to those without PMDD. While evidence based on prospective data is warranted in future, effective management is needed to improve the quality of life for women suffering PMDD.

Are mother-baby units the standard of care for the treatment of postnatal mental health disorders

C. P. Desport[1]* and R. F. Dionísio[1]

[1]Hospital de Magalhães Lemos, Unidade Local de Saúde de Santo António, Porto, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.574

Introduction: The postpartum is a high-risk period for onset and recurrence of maternal mental health disorders. If left untreated these disorders can have important consequences on mother, baby and family. When the disorder is severe or there are no conditions to manage it in the community the mother may need to be hospitalized and the gold-standard are the mother-baby units (MBU) in which mothers are co-admitted with their infant.
Objectives: We aim to explore this model of care (MBU), the pros and cons and how it has been done worldwide, so you can better understand how they work and improve the care we provide to our patients.
Methods: To this purpose we conducted a literature review by searching and analyzing papers on mother-baby units. The search was on PubMed and Google Scholar, with the following key-words: "mother-baby unit", "maternal mental health", "postpartum mental health" and "postnatal psychiatry".
Results: The MBU are considered the best practice by the National Institute for Health and Care Excellence (NICE) and their guidelines for Antenatal and Postnatal Mental Health recommend MBUs be staffed by specialist perinatal mental health staff. The postnatal period is a critical time for mother and baby binding and there is scientific evidence that separating the mother and infant during the first year could impact negatively on the developing attachment relationship and be a detrimental and traumatic experience for both. Also, by committing both mother and baby, we have an opportunity to watch and guide the mother to baby care. The United Kingdom pioneered in MBUs and in 1958 opened the first separate MBU and then France opened theirs in 1979 and Belgium in 1990.
Conclusions: To summarize, the dyad admission, allows for the mother to receive adequate treatment for her psychiatric disorder, whilst also receiving support in developing parenting skills. In the last years many countries worldwide have adopted this as standard of care, with excellent outcomes for both mother and baby.

Psychological adjustment to infertility and its effect on mental health in women

M. Mitrović[1], N. Ćirović[1]*, J. Opsenica Kostić[1], I. Janković[1], M. Guberinić[1], M. Spasić Šnele[1] and M. Trenkić[2]

[1]Department of Psychology, Faculty of Philosophy, University of Niš and [2]Faculty of Medicine, University of Niš, Niš, Serbia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.575

Introduction: Infertility represents a serious biopsychosocial crisis. Faced with infertility in a society that emphasizes parenthood as a desirable role, and driven by their own desire to become a parent, a person is forced to (re)define themselves as an adult and find their place in society. Research shows that women are more affected by this issue. Firstly, medical treatment for infertility is more uncomfortable for women than for men. Moreover, in most societies, women are considered the responsible partner for reproduction. The experience with this problem can be traumatic enough to become a reference point for identity and for attributing meaning to other experiences in one’s life.
Objectives: This research aimed to examine the mediating role of psychological problems caused by infertility in the relationship between self-stigma and the degree of integrating trauma (i.e. infertility) into one’s identity, on the one hand, and the level of depression, on the other.
Methods: The study involved 197 women with difficulties conceiving who had not yet become mothers, aged between 27 and 47 years (M=37.7; SD=5.1). The following questionnaires were used: the Female Infertility Stigma Instrument (ISI-F), designed to assess self-stigma in women facing infertility. The Centrality of Event Scale (CES) measures integrating trauma into one's identity (adapted here to measure the integration of infertility into one's identity). The Psychological Evaluation Test for Infertile Couples (PET), is aimed at assessing psychological problems in various aspects of life caused by infertility, and the Patient Health Questionnaire (PHQ-9), is used to assess the degree of depression.
Results: The results show that the zero-order correlations between the predictors, mediators, and criterion are positive and significant. Mediation analysis shows that problems caused by infertility mediate the relationship between self-stigma and the level of depression (indirect effect: ß=.292, p< .001, 95%CI = .199 - .411), and between the integration of trauma (i.e., infertility) into one's identity and the level of depression (indirect effect: ß=.147, p<.001, 95%CI = .083 - .226). In both cases, full mediation is observed. Tables and figures will be added to the poster if accepted.
Conclusions: The results indicate that the degree of internalized stigma and the integration of infertility into one's identity are significant for a person's adjustment to this problem and that, together with the level of psychological problems caused by infertility, have an effect on mental health. The study underscores the "traumatic" potential of infertility and the effect of this issue on identity and mental health. The findings could also serve as guidelines for designing psychological interventions, which should focus on the problem of self-labeling, self-blame, and the redefinition of oneself as an adult.

Mind the gap: gender differences in Attention Deficit and Hyperactivity Disorder

F. Ramalheira[1]*, F. Gonçalves[1], S. Vieira[1], R. Cohen[1], M. Cameira[1] and P. Robalo[1]

[1]Hospital Júlio de Matos, ULS São José, Lisbon, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.576

Introduction: Attention Deficit and Hyperactivity Disorder (ADHD) affects both males and females, however, sex differences can be found in presentation, epidemiology and even influence clinical management. Male-to-female ratio is different in childhood from adulthood, meaning girls with ADHD are probably less referred to medical care and underdiagnosed. Women with ADHD have more prevalence of depression and anxiety than men. Also, fluctuating levels of estrogen and progesterone interferes in symptoms and medication response
Objectives: To study sex differences regarding sociodemographic, mental health care access, and psychiatric comorbidity in a sample of patients from our ADHD outpatient clinic
Methods: We collected data from all patients who attended the Adult ADHD Outpatient Clinic of our hospital from 2017-2022 (N = 262), excluding those without written information or an ICD-11 diagnosis of 6A05 - attention deficit hyperactivity disorder (n=209). We performed a descriptive statistical analysis comparing male (n=132) and female (n=76) on sociodemographic factors, educational achievement, age of diagnosis, treatment and comorbidities
Results: Average of age was 39,4 for females (F) and 34,3 for males(M). Levels of primary education were 5% for both, secondary education 41% F and 53% M, and tertiary education 41% F vs 37% M. 30% F and 37% M had failed at least once during their academic path. 26% F vs 25% M were students, 45% F vs 48% M were working actively and 8% F vs 15% M were unemployed. Only 8% F had an ADHD diagnosis during childhood and adolescence whether 41% of M had a history of early diagnosis and/or treatment. At least once psychiatric comorbidity was found in 75% F and 67% M, and medical comorbidities were present in 36%F and 44% M. Comorbid psychiatric diagnosis were anxiety disorders (36% F vs 26% M), depressive disorders (29% F vs 18% M), intellectual developmental disorders (5% F vs 13% M), substance abuse disorders (5% F vs 9% M), bipolar disorder (11% F vs 5% M), and autism spectrum disorders (3% F vs 5% M). In F, 75% were treated with stimulants and 11% with non-stimulants as in M 80% were treated with stimulants and 8% with non-stimulants. 37% F vs 24% M maintain follow-up, while 50% F vs 61% M abandoned it
Conclusions: In our study, women were less diagnosed in childhood and adolescence than men, regardless of failing in school in a similar percentage, which reflects underdiagnose in girls. Women had more percentage of psychiatric comorbidities, including anxiety, depressive, and bipolar disorders, whereas men had more prevalence of substance abuse and intellectual developmental disorders, meaning that women with ADHD are more prone to develop mood-related comorbidities than men. The percentage of follow-up abandon is also lower on women which indicates that, in spite of being less referred to medical care for ADHD, they are probably more likely to adhere to treatment

The association between childhood trauma and facial emotion recognition in women with premenstrual dysphoric disorder

A. Vardiampasis[1]* and C. Gramandani[1]

[1]Mental Health Center, General Hospital of Rethymno, Crete, Rethymno, Greece
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.577

Introduction: Facial emotion recognition is a fundamental component in social interaction. Facial emotion recognition is disturbed both in women with Premenstrual Dysphoric Disorder (PMDD), and in those with a history of childhood trauma. PMDD affects up to 5% of women of childbearing age, exert influence on women's recognition of emotions, and on the emotion recognition processing. Women with PMDD are more likely to have a history of childhood trauma.
Objectives: To explore whether there is a link between a history of trauma and the perception of emotions in women with PMDD. We hypothesize that women with PMDD and a history of childhood trauma will show larger deficits in emotion recognition compared to women with PMDD but without a history of childhood trauma.
Methods: Data were derived from a sample of forty women diagnosed with PMDD (18-30 y.o., right handed, educational level >9y., regular cycle duration), who have visited Mental Health Centre of Rethymno (participants completed the Premenstrual Syndrome Questionnaire). The participants completed the Childhood Trauma Questionnaire (CTQ), which measures five types of maltreatment experiences. Three types are related to abuse (physical, sexual and emotional) and two to physical and emotional neglect. The Emotion Recognition Task (ERT) was also administered. ERT is a computer-generated paradigm for measuring the recognition of six basic facial emotional expressions: anger, disgust, fear, happiness, sadness, and surprise. During this test, video clips of increasing length are presented.
Results: The majority of the participants (82.5%) reported a history of maltreatment during childhood. Women without trauma, when they completed the ERT did not show any significant emotion dysregulation. On the contrary, maltreated women, especially physically or sexually abused, had a distorted perception of emotions expressed on adult faces. Happiness is less detected, whereas fear and anger are recognized more rapidly and at a lower intensity compared to women not exposed to childhood trauma. The higher the score in abuse, the higher the emotion dysregulation is.
Conclusions: The main conclusion of this study contributes to the current knowledge on the link between the long-term effects of childhood trauma both to PMDD and to emotion dysregulation. Women with PMDD are more likely to have a history of childhood trauma, which is associated with poorer performance in facial emotion recognition. Trauma, however, is a treatable factor with. Therefore, interventions targeting both to heal trauma and to promote adaptive emotion regulation strategies, could be encouraged to improve the capability of women with a history of childhood trauma to challenge premenstrual symptoms.

The effect of experienced discrimination and internalized homophobia level in gay and bisexual men on social anxiety level, self-esteem and quality of life

B. Yağcı[1]* and F. İzci[2]

[1]State Hospital, Ministry of Health, İzmir and [2]Training and Research Hospital, Ministry of Health, İstanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.578

Introduction: Minority groups in terms of sexual orientation are exposed to specific stressors, unlike the stressors of the general population. Discrimination, stigma, prejudice and violence are more common in minority groups in terms of sexual orientation than heterosexuals, and they affect mental health negatively. Minority stress factors such as perceived discrimination, self-stigmatization and internalized homophobia have negative effects on mental health.
Objectives: External and internal minority stressors, which are associated with social anxiety like many mental illnesses, are also associated with self-esteem and quality of life. Minority stress factors should also be well understood in order to understand the consequences they cause. In this study, it was aimed to examine the relationship between discrimination and internalized homophobia experienced in gay and bisexual men with social anxiety, self-esteem and quality of life.
Methods: 85 participants who defined themselves as gay or bisexual man were included in the study.The study is cross-sectional and descriptive, and the participants were reached by the snowball method.Sociodemographic and clinical data form, including the experienced discrimination questions prepared by the researcher, Internalized Homophobia Scale, Libowitz Social Anxiety Scale, Social Interaction Anxiety Scale, Rosenberg Self-Esteem Scale, World Health Organization Quality of Life Scale Short Form Turkish Version (Whoqol-bref Tr) has been applied.The relationship between experienced discrimination in the sample and internalized homophobia; social anxiety, self-esteem and quality of life were examined separately.
Results: It was found a significant relationship between experienced discrimination and social anxiety levels, an inverse relationship was found with self-esteem. A same-way relationship was found between internalized homophobia and social anxiety levels, while an inverse relationship was found with self-esteem. Experienced discrimination and internalized homophobia were both found to be inversely related to quality of life.
Conclusions: In our study, it was found and discussed that experienced discrimination in gay and bisexual men was positively related to the level of social anxiety, and negatively related to self-esteem and quality of life;similarly there was a positive relationship between the level of internalized homophobia and the level of social anxiety, and a negative relationship between self-esteem and quality of life.When these results are evaluated, it is understood that discrimination experiences and negative mental consequences should be taken into account when evaluating homosexual and bisexual men who are minorities in terms of sexual orientation in mental health clinics and practices, psychological support process, preventive mental health practices and policies to be developed.

Prevalence of drug abuse and it's perceived effect on the mental health and academic performance of secondary school students in Bauchi State Nigeria.

R. M. Bawa[1]*, H. I. Gomma[2] and A. A. Abdullateef[3]

[1]Psychiatric Nursing, Federal university of health sciences, Azare, Bauchi; [2]Nursing sciences, Ahmadu Bello University Zaria, Kaduna and [3]Psychiatry, college of medical sciences, Ahmadu Bello University, zaria, Nigeria
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.579

Introduction: The study was designed to determine the prevalence of drug abuse and its perceived effect on the mnetal health and academic performance of secondary school students in Bauchi State, Nigeria.
Objectives: Objectives of the Study
The aim of this study is to examine the prevalence of drug abuse and its perceived effects on the mental health and academic performance of secondary schools student in Bauchi state. The specific objectives are:
1. To determine the prevalence of drug abuse among secondary school students in Bauchi metropolis.
2. To identify the perceived drugs commonly abused by students in secondary schools.
3. To investigate perceived reasons secondary school students abuse drug in Bauchi metropolis.
4. To investigate the perceived negative effect of drug abuse on the mental health and school performance of the students in secondary schools of Bauchi metropolis.

Methods: The study adopted a cross sectional descriptive design. Multistage sampling procedure was used to select 26 Secondary Schools in Bauchi state. The schools have a combined population of 11,439 students. The instrument for Data collection was a WHO Youth Drug Survey (WHOYDSQ) and drug abuse screening test (DAST) adapted questionnaire and a sample size of 399 was obtained using Yamane formula. The reliability of the instrument was established using a test and re-test. Data generated analysed using frequency distribution tables, cross tabulation and chi square.
Results: Out of 399 copies of the questionnaire distributed, 372 were correctly filled and analyzed. Majority (80%) of the respondents were between 18-20 years. More than half, 208 respondents (55.9%) reported to have used drug for non-medical reasons once or more in the past one year. The commonest substances abused were codeine, cough syrup, cannabis and tramadol. More than half of the users of each of the substances take it occasionally. Among the respondents, 42.8% who used psychoactive substances were introduced to the substance by their friends. Major reasons for using psychoactive substance include reduction of stress (37.1%), out of curiosity (28%) and memory improvement and retention (26.6%). There was significant difference ($p < 0.05$) in the academic performance of the respondents that abuse drug and those that do not.
Conclusions: In conclusion the prevalence of substance abuse among Secondary School students was high (55.9%) as such

government, parents, teachers, stakeholders and the community leaders needs to join hands to fight and address the problem.

Problem substance use in young adults: The impact of adverse life experiences

R. Fusco

Social Work, University of Georgia, Athens, United States
doi: 10.1192/j.eurpsy.2025.580

Introduction: Data from community samples have shown that the risk of negative outcomes during the transition to adulthood is greater for those who engage in substance use. Alcohol use is common among young adults in the U.S., with 82% using in the past year and 34% engaging in havy episodic drinking . Marijuana is the second most widely used substance among young adults and regular use has been connected to an increased risk of anxiety and depression, and linked to both psychoses and poorer outcomes in people diagnosed with schizophrenia.
Objectives: The goal of the current study is to understand the role of adverse childhood experiences (ACEs) on the likelihood of frequent marijuana and alcohol use among a sample of low-income young adults (*N*=182) in the U.S.
Methods: Some original ACE study items were examined, such as types of child maltreatment. Additional items were added, including time spent in foster care as a child, involvement in a serious accident, experienced a serious injury, violent death of a family member or friend, and witnessed a serious injury or death. Frequent alcohol and marijuana use was defined as once a week or more in the past 30 days. Logistic regression models were developed to understand the magnitude of the contribution of each individual factor on the frequent use of both alcohol and marijuana. Separate models were developed to predict marijuana use and alcohol use.
Results: The participants' mean age was 20.5. The majority of the sample identified as Black (59%) or White (34%). A little more than half (53%) identified as female. Thirty percent reported using alcohol and 35% reported using marijuana at least once a week in the past 30 days.
The logistic regression model predicting frequent alcohol use showed several significant independent variables. Time in foster care (OR=2.88), childhood sexual abuse (OR=2.59), and childhood emotional abuse (OR=4.01) were all significant. Additionally, having a close family or friend who died violently (OR=6.63) and witnessing a serious injury or death (OR=2.92) were statistically significant.
The model predicting frequent marijuana use showed similar significant independent variables. Time in foster care (OR=3.48), childhood physical abuse (OR=3.67), childhood emotional abuse (OR=9.65), and having a close family member or friend who died violently (OR=4.99) all significantly increased the odds of marijuana use.
Conclusions: Study results show the sustained negative impact of both child maltreatment and out-of-home placement. While less studied than other forms of maltreatment, emotional abuse was predictive of both alcohol and marijuana use. Youth who experienced violence in their community also showed a greater likelihood of alcohol and marijuana use. These results highlight the importance of identifying and addressing child maltreatment. Efforts to prevent and address substance use in young adults should take experiences of violence and abuse into account.

Hospital Clínic de Barcelona, ICN, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.581

Introduction: The significant psychological burdens posed by cannabis use on adolescents and young adults, make them a target for interventions to enhance their health literacy regarding patterns of cannabis use (dose and frequency) that lead to higher health risks. Critically incorporating this information is known as health literacy (HL). Within the Cahly project we have designed a psychoeducational intervention to enhance HL regarding cannabis use among students aged 15-25 years old.
Objectives: Explore the efficacy of the intervention in improving HL among the students.
Methods: Prospective, randomised controlled trial with a duration of 1-month. 50 high-school centers and universities located in Barcelona were offered to participate. In those accepting, students were randomised to the experimental (received the intervention) or control groups (did not receive it). Both groups completed a baseline questionnaire on: HL, HL on cannabis use, substance use in the previous year and in the previous month, as well as sociodemgraphic data. These questions were repeated after one month of entering the study. In the present stage, we will present the baseline HL level (means, %), and the comparison among groups for the follow-up measures (using either Pearson's Chi-squared test or Fisher's exact test as appropriate, group mean comparisons utilized either the Student's t test or Wilcoxon rank sum test,).
Results: 300 students have so far finalised the study. Baseline results indicate low levels of general health literacy, and lower knowledge regarding HL on cannabis, with a predominance of use of informal sources of information. Those receiving the intervention improve significantly their knowledge regarding the patterns of cannabis use that lead to higher risks. However, the intervention did not affect their patterns of substance use.
Conclusions: We propose an innovative intervention aiming to disseminate a definition of cannabis risky use among a vulnerable population such as youth. Preliminary results are promising.

Semantic similarity analysis in speech samples of patients with first-episode bipolar disorder

B. Arslan[1]*, E. Kizilay[1] and E. Bora[1,2,3]

[1]Department of Neurosciences; [2]Department of Psychiatry, Dokuz Eylul University, Izmir, Türkiye and [3]Department of Psychiatry, University of Melbourne and Melbourne Health, Melbourne, Australia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.582

Introduction: Individuals with first-episode bipolar disorder (FEBD) may have language abnormalities and sub-threshold formal thought disorder (FTD). Natural language processing (NLP) methods that have been shown to assess FTD in psychosis can be used in the early stages of bipolar disorder (BD).
Objectives: The purpose of this study was to examine the differences between FEBD and healthy controls (HC) utilizing NLP methods.
Methods: Speech samples were collected from 20 FEBD and 20 HC while describing eight Thematic Apperception Test images. The manually transcribed text was then processed using word2vec to generate vectors. The semantic similarity between words was computed utilizing a moving window method to windows ranging in size from 5 to 10. Finally, the average, variance, maximum, and minimum of these similarities were calculated.
Results: All mean similarities (windows of 5 to 10) were significantly higher in FEBD (p< .001, p=0.001, p=0.002, p=0.002, p=0.003, and p=0.004, respectively). Additionally, all variances of similarities were highly significant and were increased in FEBD (all p values< .001). Regarding maximum values, except for the window of 5, all of the remaining windows were significantly higher in FEBD (all p values <.05.).
Conclusions: Our findings indicate that semantic similarity increased in the FEBD group compared to HC. Overall, NLP methods offer an easily applicable approach for assessing FTD in FEBD and discriminating between FEBD and HC.

Evidence-based interventions for bipolar disorder: an open-access platform to guide treatment decisions based on efficacy, safety, and patient preferences.

M. De Prisco[1]*, V. Oliva[1], C. Gosling[2,3], S. Cortese[4], F. Jess[5], E. Vieta[1] and M. Solmi[5]

[1]Bipolar and Depressive Disorders Unit, FRCB-IDIBAPS, Barcelona, Spain; [2]DysCo Lab, Université Paris Nanterre, Nanterre; [3]Laboratoire de Psychopathologie et Processus de Santé, Université de Paris, Boulogne-Billancourt, France; [4]Centre for Innovation in Mental Health, School of Psychology, Faculty of Environmental and Life Sciences, University of Southampton, Southampton, United Kingdom and [5]Department of Psychiatry, Ottawa Hospital Research Institute, University of Ottawa, Ottawa, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.583

Introduction: Bipolar disorder (BD) is a psychiatric condition characterized by a wide range of symptoms, for which many interventions have been proposed. Although the literature contains numerous meta-analyses (MAs) and network meta-analyses (NMAs) summarizing this evidence, the large volume and variability of information can make it difficult to apply in daily clinical practice, guide researchers, or inform the development of clinical guidelines.
Objectives: To offer a freely accessible platform, developed within the U-REACH framework, providing updates on the latest therapeutic strategies for BD in terms of efficacy and safety, aligned with patient preferences. Informed by a living umbrella review, the platform aims to grade the current evidence to support informed decision-making.
Methods: We conducted an umbrella review by searching PubMed, PsycINFO, and the Cochrane database up to December 31, 2023, for (N)MAs of randomized controlled trials investigating interventions for BD. Each association was assessed using the GRADE. Effect sizes were standardized into equivalent standardized mean differences (eSMD), with eSMD>0 indicating clinically positive effects and eSMD<0 indicating clinically negative effects. The results are made available on an open-access online platform. Users can filter data by age group, BD stage, intervention, effect size, outcome, comparison, type of meta-analysis, GRADE evidence level, and (N)MA quality. For any filter combination, users can visualize key interventions, outcomes, and a forest plot with eSMD. The database will be regularly updated. Additionally, a preference-based tool allows users to rank safety outcomes by importance (0-10) and the system will recommend medications based on these preferences.
Results: From the 4,352 records retrieved, we included 71 (N)MAs evaluating the effects of pharmacological (n=87), brain stimulation (n=13), psychosocial (n=8), and circadian rhythm-based therapies (n=3), on 132 efficacy (n=85) and safety (n=47) outcomes. For the preference-based tool, we included 10 first-line interventions for at least one mood state of BD (aripiprazole, asenapine, cariprazine, lamotrigine, lithium, lurasidone, paliperidone, quetiapine, risperidone, valproate) and 15 safety outcomes based on clinical judgment (e.g., akathisia, weight increase, QTc prolongation, insomnia), resulting in 150 potential combinations.
Conclusions: This platform represents a pioneering approach to delivering the most complete evidence on interventions for BD. With its regular updates, it provides clinicians and researchers with a freely accessible resource to guide treatment decisions based on efficacy, safety, and patient preferences. This tool aims to support the development of future guidelines, facilitate ongoing professional education, and ultimately improve the quality of care for individuals with BD.

Temperament in People with Familial High Risk for Bipolar Disorder and Psychosis: An exploration of Schizotaxia and Cyclotaxia

M. Demir[1]*, M. S. Eyüboğlu[1], E. Cesim[1], Ç. Çimentepe-Sezer[2], B. Yalınçetin[1], B. Verim[1], E. T. Süt[3] and E. Bora[1,2,4]

[1]Department of Neurosciences; [2]Department of Psychiatry; [3]Department of Child and Adolescent Psychiatry, Dokuz Eylül University, İzmir, Türkiye and [4]Department of Psychiatry, University of Melbourne, Melbourne, Australia

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.584

Introduction: Research on temperament in individuals with familial high risk for psychosis (FHR-P) and bipolar disorder (FHR-BD) suggests that specific temperament patterns may mirror characteristics of the associated disorders. Terms such as schizotaxia and cyclotaxia describe these patterns: schizotaxia is linked to traits such as cognitive disorganization and social withdrawal seen in those at risk for psychosis, while cyclotaxia involves emotional instability and reactivity associated with bipolar disorder.
Objectives: This study aims to investigate the relationship between temperament traits associated with psychosis and bipolar disorder as suggested in the concept of schizotaxia and cyclotaxia.
Methods: We recruited a total of 94 participants, comprising 29 people at familial high risk for psychosis (FHR-P), 41 people at familial high risk for bipolar disorder (FHR-BD), and 24 controls (HC). Participants from familial high-risk groups were identified through patient records or outpatient settings at Dokuz Eylül University. Several self-report measures are selected to investigate the temperament traits of schizotypy and cyclothymia. Those measures listed as; the Schizotypal Personality Questionnaire (SPQ), Behavioral Inhibition System/Behavioral Activation System (BIS/BAS) Scale, Temperament Evaluation of Memphis, Pisa, Paris and San Diego-auto questionnaire version (TEMPS-A), Pittsburgh Sleep Quality Index (PSQI), Barratt Impulsiveness Scale (BIS). One-way ANOVA is used to analyze the data using Jamovi Version 2.6.2.0.
Results: FHR-P individuals, but not FHR-BD, had significantly higher scores of depressive($p<.001$), cyclothymic ($p=.005$) and anxious($p=.002$) temperament than HC in TEMPS-A subscales. Both familial groups had significantly higher scores in activation($p=.001$) but not in inhibition in BIS/BAS. Moreover, they had worse sleep quality indicated by significantly higher PSQI ($p=.014$) scores. BIS scores and SPQ total scores do not significantly differ across groups however, FHR-P had significantly higher scores in negative subscores($p=.032$) of SPQ than HC.
Conclusions: Our findings show significant differences in the FHR-P group across most temperament scores, indicating a greater vulnerability to schizotypal and cyclothymic traits. This may result from various factors, such as participants being recruited from outpatient psychiatric settings. Both familial groups also demonstrated lower educational levels and premorbid IQ scores on the WAIS, with more pronounced differences in the FHR-P group compared to the FHR-BD group. Additionally, the unequal sample sizes among the groups could affect the results. Therefore, further research is needed to account for the influence of common psychiatric conditions associated with participants' help-seeking behaviour and to ensure better educational matching with healthy controls.

Risk of Respiratory Disease in people with Bipolar Disorder: A Systematic Review and Meta-Analysis.

A. Jimenez[1,2*], D. Laguna[1,2], M. I. Alarcón[1], M. Reyes[1], M. J. Jaén[2,3] and F. Sarramea[1,2]

[1]Hospital Univeristario Reina Sofía; [2]IMIBIC and [3]Univesity of Córdoba, Córdoba, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.585

Introduction: People with bipolar disorder (BD) have an increased risk of premature mortality, and the respiratory mortality rate is higher than those of the general population. However, the evidence on respiratory disease in this population has not been meta-analyzed.
Objectives: To systematically review and meta-analyze the frequency of respiratory diseases in patients with BD and to compare prevalence and Odds Ratio (OR) with the general population.
Methods: A systematic literature search was conducted in Pubmed, PsycINFO, Scielo and Scopus from inception to June 2, 2023, and a snowball search of reference and citation lists was conducted. Inclusion criteria were studies reporting diagnoses of respiratory diseases (asthma, chronic obstructive pulmonary disease (COPD), pneumonia, lung cancer and tuberculosis) in people with BD according to operationalized criteria and where possible, control group. This study followed Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) and MOOSE reporting guidelines. A pair of reviewers independently extracted data using a predefined data extraction form and a senior co-author was consulted in cases of disagreement. The risk of bias and methodological quality was assessed using the adapted Newcastle-Ottawa scale.
Results: Of the 2,158 articles screened, 20 including 962,352 people with BD and 37,340,405 control group, met the inclusion criteria (see Figure 1). Prevalence and OR of respiratory disease in people with BD was the main outcome as percentage point estimates with corresponding 95% CIs. In people with BD, the prevalence of COPD was 9.14% (95%CI: 6.61%-12.5%), asthma 6.4% (95%CI: 4.56%-8.91%), pneumonia 2.78% (95%CI: 2.51%-3.08%) and lung cancer 0.44% (95%CI:0.23%-0.84%) (see Figure 2). Compared to the general population (see Figure 3), people with BD had significantly higher rates of COPD (OR: 1.73; 95% CI: 1.40-2.14), showing an increased rate in younger and female patients; asthma (OR: 1.91, 95% CI: 1.25-2.94), with a greater rate in younger patients; and pneumonia (OR: 2.82, 95% CI: 1.33-5.99).

Image 1:

Figure 1: Study screening and selection flowchart

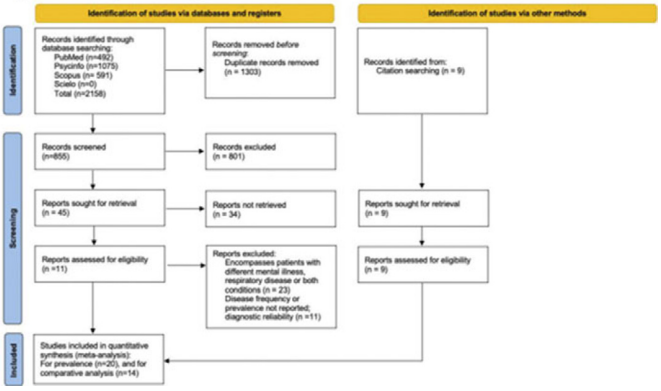

Image 2:

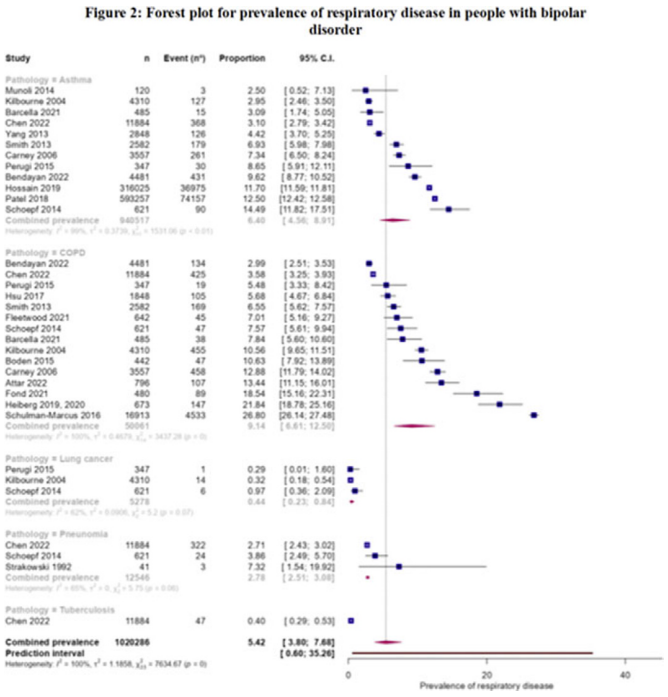

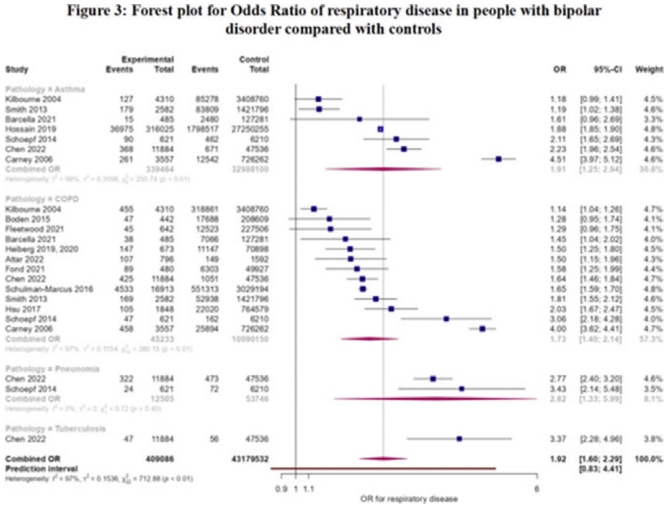

Image 3:

Conclusions: In the first meta-analysis on the topic, BD was associated with an increased risk of respiratory illness versus the general population. In COPD and asthma, young people and women are at particular risk. Prevention programs are urgently needed.

Prevalence of Dermatologic Side Effects of Mood Stabilizers in Bipolar Disorder: A Systematic Review and A Meta-Analysis

F. Pampaloni[1,2], M. Ercis[1], D. M. R. Davis[3], M. Starace[2], B. M. Piraccini[2], A. Ozerdem[1], B. Singh[1], M. A. Frye[1], J. Blacker[4] and M. Veldic[1]*

[1]Psychiatry and Psychology, Mayo Clinic, Rochester, United States; [2]Unit of Dermatology, IRCCS University Hospital of Bologna, Bologna, Italy; [3]Department of Dermatology, Mayo Clinic, Rochester and [4]Psychiatry and Behavioral Sciences, University of Minnesota, Minneapolis, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.586

Introduction: Bipolar disorder (BD) is a chronic illness affecting approximately 2-3% adults worldwide. Mood stabilizers, such as lithium, valproate, carbamazepine, and lamotrigine are mainstays of the treatment. Despite their benefits, mood stabilizers carry a risk of side effects, which can lead to treatment discontinuation and non-adherence rates ranging from 10 to 60% in BD patients (Dols *et al.* Int Clin Psychopharmacol 2013; 28, 287-296). Dermatologic side effects, also known as cutaneous adverse drug reactions, are particularly distressing, often impacting patients' self-esteem and social interactions, and contributing to non-compliance. These reactions can range in severity from mild rashes, acneiform eruptions, hair loss and psoriasis to severe, life-threatening conditions like Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) (Mitkov *et al.* Psychosomatics 2014; 55, 1-20).
Objectives: Despite the well-documented association between mood stabilizers and dermatologic adverse effects (AE), the overall prevalence of these reactions across mood stabilizers remains unclear. This systematic review and meta-analysis aims (1) to estimate the prevalence of dermatologic AE associated with mood stabilizer (lithium, valproate, carbamazepine and lamotrigine) use in patients with BD, and (2) to summarize the available evidence on the onset and timing of these reactions.
Methods: We searched Ovid MEDLINE®, Embase, Cochrane Library, Web of Science, Scopus, and PsycINFO from 1970 onward for studies on dermatologic AEs in BD patients treated with lithium, valproate, carbamazepine, or lamotrigine (CRD42022357268). Study selection, data extraction, and bias risk assessment were performed by two reviewers. Meta-analyses were conducted to estimate the prevalence rates for dermatologic AEs.
Results: The initial database searches yielded 5,354 studies. 47 articles were deemed relevant and included in this systematic review. Study designs included 16 randomized controlled trials, 10 non-randomized open-label trials, 12 cohort studies, and 9 cross-sectional studies.
Lithium was associated with acneiform eruptions in 4.4% (95% CI: 1.0-17.0%), rash in 1.8% (95% CI: 0.7-4.8%), and hair loss in 1.7% (95% CI: 0.4%-6.4%) of patients. For valproate, hair loss was observed in 4.6% of patients (95% CI: 3.0-6.7%) and rash in 2.9% (95% CI: 1.6-5.3%). Carbamazepine was associated with rash in 6.0% of patients (95% CI: 4.4-7.6%), but severe reactions such as SJS and TEN were not reported. Lamotrigine had the highest rash prevalence with 9.2% (95% CI: 7.2-11.8%), while severe reactions were rare (0.04%, 95% CI: 0.00-0.63%).
Conclusions: Mood stabilizers showed varying levels of dermatologic AEs, but severe reactions were rare. Future studies should explore factors influencing these outcomes, their impact on quality of life and treatment participation, and potential management strategies.

Convergence of Phenomenology and Neuroscience in Autism Therapy: A Case Study of Exchange and Development Therapy

S. Bora[1,2,3]

[1]Tours Regional University Hospital, Tours, France; [2]University of Central Lancashire, Preston, United Kingdom and [3]Cambodian Children's Fund, Phnom Penh, Cambodia
doi: 10.1192/j.eurpsy.2025.587

Introduction: This abstract explores the integration of phenomenology and neuroscience in understanding and managing Autism Spectrum Disorder (ASD) through Exchange and Development Therapy (EDT). EDT, developed by Professor Gilbert Lelord, focuses on restoring impaired functions in children with autism through principles of calm, receptiveness, and reciprocity.
Objectives: This study investigates the similarities between EDT principles and phenomenological concepts like intersubjectivity, intercorporeality, and intentionality, aiming to demonstrate the value of phenomenology in understanding autism.
Methods: The research involved a two-part approach:

1. Theoretical argumentation, explaining EDT principles and relevant phenomenological concepts in autism.
2. Phenomenological analysis of autobiographies of individuals with autism to identify recurring themes and align them with EDT principles.

Results: The study revealed a significant convergence between EDT principles and phenomenological concepts. Calmness in EDT aligns with intercorporeality, receptiveness with intentionality, and reciprocity with intersubjectivity. This convergence suggests that phenomenology is crucial for understanding the lived experiences of individuals with autism, which can inform and enhance neuroscience-based therapeutic approaches.
Conclusions: The integration of phenomenology and neuroscience offers a promising avenue for developing more effective and compassionate autism therapies. By incorporating the subjective experiences of individuals with autism, therapists can tailor interventions that resonate with their unique phenomenological worlds, leading to improved therapeutic outcomes. This research advocates for a more holistic and individualized approach to autism treatment, highlighting the indispensable role of phenomenology in contemporary psychiatry.

The right to mental health protection and its status in European Union primary law

M. Burdzik[1,2]

[1]Dr. Krzysztof Czuma's Psychiatric Center and [2]Institute of Law, University of Silesia, Katowice, Poland
doi: 10.1192/j.eurpsy.2025.588

Introduction: Mental health is one of the fundamental personal values of every human being. Thus its protection should be one of the primary obligations of every state. To ensure common standards in aforementioned matter, it is necessary to exist an universal (supranational) grounds and rules for the protection of mental health, as well as the protection of people with mental disorders rights. Especially that, mental disorders are found all over the world, and in an age of globalisation and migration, borders are only a legal construct. In the Western European axionormative order, one of the factors shaping common normative standards is European Union law.
Objectives: The aim of this study is to identify the norms of European Union primary law from which the right to mental health protection can be derived (directly or indirectly), with a subsequent assessment of their adequacy.
Methods: The study is based on a dogmatic analysis of the primary legislation of the European Union (i.a. the founding Treaties or the Charter of Fundamental Rights of the EU - CFR) with analysis of the relevant literature of the subject and jurisprudence of the Court of Justice of the European Union.
Results: No provision of EU primary law explicitly statutes a 'right to mental health protection'. Currently, this right can be derived indirectly from norms relating to its particular aspects - e.g. the protection of mental integrity (Article 3 of CFR or Article 165 (2) of the Treaty on the Functioning of the European Union - TFEU), the removal of threats to mental health (Article 168 (1) TFEU) or the prohibition of discrimination on grounds of disability (Article 10 TFEU).
Conclusions: The current regulations are incomplete and therefore inadequate. The protection of mental integrity or the fight against discrimination are necessary for mental health (well-being) of entities, but do not fully cover the latter concept. The strengthening of the legal position of people with mental disorders requires the introduction into EU legislation of a comprehensive regulation that statutes the right to mental health protection, together with mechanisms for its enforcement against state authorities.

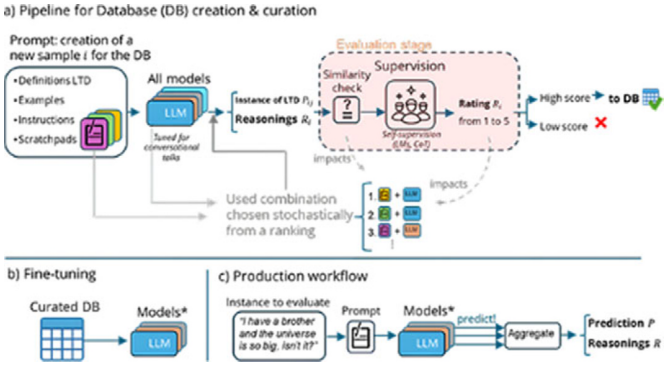
LLM-Powered Evolutionary System for Generating Large-Scale Databases in Speech-Related Psychiatric Conditions

E. Gutierrez Alvarez[1,2], P. Cano[1]*, J. M. Vera[1] and E. DeFraites[3,4,5]
[1]Universidad Politécnica de Madrid, Madrid, Spain; [2]MIT linQ - Massachusetts Institute of Technology, Cambridge; [3]Mental Health Intensive Case Management, Greater Los Angeles VA Healthcare System; [4]Department of Psychiatry, UCLA - University of California, Los Angeles, Los Angeles and [5]MIT linQ - Massachusetts Institute of Technology, Cambridge, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.589

Introduction: In clinical studies on psychosis prediction, small sample sizes have been a persistent issue. Most studies rely on limited data, lack cross-validation, and use poor model strategies, leading to overfitting and overestimated accuracy. This challenge also affects traditional studies, where recruiting few participants introduces biases. Data harmonization is another hurdle, especially in speech analysis, which is crucial in psychiatry for conditions like psychosis, aphasia, and PTSD, but suffers from inconsistent methodologies across databases.
Objectives: Our goal was to develop an method using Large Language Models (LLMs) to create diverse, synthetic speech datasets, addressing these challenges: 1. Develop an evolutionary system for optimizing high-quality speech data generation. 2. Incorporate contrastive learning for improved model decision boundaries. 3. Provide a methodology for training classification models and conducting cross-cultural studies. 4. Create a large-scale, diverse database of synthetic psychiatric speech samples.
Methods:
Results: We presented a case study focused on the phenomenon of "Illogical Thinking," a language disorder proven to correlate with psychosis risk. Results:

1. Top-performing LLMs: Claude Sonnet 3.5 and GPT-4.
2. Optimal prompt structure determined
3. Database size: 3,000 samples
4. Computational efficiency: 200 evolutionary steps, 400 API calls
5. High data quality and diversity
6. Useful rationales for developing explainable models

Image 1:



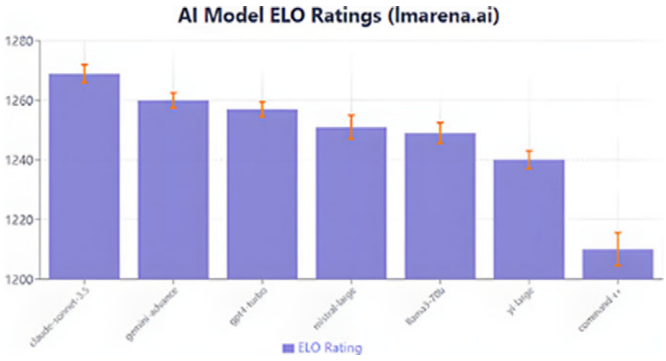


Image 2:

Conclusions: Our findings suggest that this approach could significantly benefit psychiatric research by addressing the challenges of small sample sizes and data inconsistency. The method shows promise for creating more reliable and generalizable predictive models, which could lead to advancements in mental health care practices. The system's flexibility indicates potential applications beyond our case study, possibly extending to other areas where data scarcity has impeded progress.

Is it possible for artificial intelligence (AI) to develop a personality?

E. Molchanova
Psychology, American University in Central Asia, Bishkek, Kyrgyzstan
doi: 10.1192/j.eurpsy.2025.590

Introduction: The development of artificial intelligence (AI) has led to significant advancements in various fields, including mental health applications. As AI technologies like ChatGPT continue to evolve, questions have arisen about whether AI can eventually develop a true personality, and what implications this might have for fields such as psychology and psychiatry. Isaac Asimov's ideas about AI and the Turing test have gained renewed attention, yet these frameworks do not address the core psychological components such as empathy, emotion, and personal interaction—key elements in therapeutic settings.
Objectives: This article explores whether AI could develop a personality and replace human therapists in psychological counseling and psychiatry. Specifically, it aims to evaluate AI's current capabilities in providing emotional and psychological support and to address whether AI can evolve to meet therapeutic practice's deeper, human-centered requirements.
Methods: The analysis is based on reviewing current AI applications in mental health, such as AI-based therapy platforms for post-traumatic stress disorder (PTSD), which provide symptom management tools and promote adaptive coping strategies. These applications were compared to the human therapist's role,

focusing on emotional interaction, empathy, and the therapeutic relationship. Additionally, the philosophical and psychiatric aspects of personality formation in both humans and AI were examined.
Results: AI systems have made progress in simulating therapeutic techniques, providing guidance, and mimicking emotional responses. They can support symptom relief and enhance coping strategies, especially in areas where human therapists are scarce. However, AI's ability to engage with deeper aspects of the therapeutic process, such as emotional empathy and personal connection, remains limited. AI lacks subjective experience, emotional depth, and self-awareness—essential factors for forming a genuine personality.
Conclusions: While AI has the potential to augment clinical practice, it cannot replace the human element in therapy. The development of AI-based tools is valuable for symptom management, but psychotherapy is inherently rooted in human connection, intuition, and emotional engagement—qualities AI does not possess. For AI to truly replace human therapists or develop a personality, significant advancements in consciousness and emotional cognition would be required, which remain speculative at this stage. Thus, AI will likely continue to serve as a supportive tool rather than a replacement for human therapists in the foreseeable future.

The Role of Gut Microbiome in Psychiatric Disorders

J. T. Coelho[1]*, A. L. Ramos[1], B. C. da Silva[2] and S. Timóteo[1]
[1]São João Local Health Unit and [2]Santo António Local Health Unit, Porto, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.591

Introduction: Emerging evidence on the bidirectional connection between gastrointestinal microbiota and brain, through the gut-brain axis, and its influence on mental disorders makes the gut microbiota a potential target for novel therapeutic approaches.
Objectives: We aim to study and synthetize the current data about the influence of gut microbiome on psychiatric disorders.
Methods: Our literature research focused on some of the most significative English-written articles published in the last decade.
Results: Most of the relevant literature suggests that the presence of a healthy and diverse gut microbiota is essential to normal cognitive and emotional processing. Also, it has been shown that consumption of probiotics can modify the functional activity of the areas in the brain that are implicated in cognitive functions.
The literature also supports that stress can change gut permeability as well as the composition of gut microbiota resulting in a pro-inflammatory profile of cytokines produced by gut microbiota. Besides, gut microbes can modulate the stress response and the level of anxiety through alterations in serotonin signaling.
It has been also demonstrated that in animal models of depression the composition of gut microbiota was changed. On the other hand, other studies demonstrated certain probiotics can attenuate depressive symptoms in rodent models.
Regarding eating disorders, Anorexia Nervosa seems to have impact on the gut microbiota balance through restrictive diets and the abrupt change in diet during nutritional rehabilitation. The use of prebiotics, probiotics, antibiotics or faecal transplantation looks promising as important novel adjuvant treatments.
Conclusions: The effect of gut microbiota on several mental disorders is supported by a increased volume of experimental data. However, research in this field is still unfolding and more studies should be performed to apply new techniques focusing on gut-brain axis in clinical practice.

Psychedelic-assisted therapy for functional neurological disorders: a review of the literature

T. F. Fernandes[1]*, J. G. Freire[1], M. C. Pais[1] and C. Pissarra[1]
[1]Centro de Responsabilidade Integrada de Psiquiatria, Unidade Local de Saúde de Coimbra, Coimbra, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.592

Introduction: Functional neurological disorders (FND), also referred to as conversion disorder or psychogenic neurological disorders, are one of the most common and disabling conditions in the neurology practice field, with very limited treatment options. FNDs present with sensory and/or motor symptoms that can mimic other neurological conditions, but appear to be related to recognizable psychological factors and are thought to occur via mechanisms other than those related to identifiable structural neuropathology. This condition has very limited treatment options, but there is preliminary evidence that psychedelic-assisted therapy (PAT) might be effective in a growing number of psychiatric disorders, including FNDs.
Objectives: We aim to review the current literature regarding the role of psychedelic-assisted therapy in the treatment of functional neurological disorders.
Methods: We search PubMed with the following keywords: psychedelics, functional neurological disorder and conversion disorder.
Results: Only nine studies were published, between 1954 and 1967, reporting the use of psychedelics in the treatment of FNDs, with a total of 22 patients, of which 69% (n = 18) were found to have made at least some recovery, though the included studies were of low quality, often lacking control groups and valid outcome measures.
Conclusions: There is a lack of evidence for the efficacy of PTA on the treatment of FNDs. Nevertheless, the discussion remains, as several abnormalities of the default mode network activity (DMN) have been reported in patients with FND and many of the proposed

therapeutic benefits of psychedelics have been theorized to relate to their action on the DMN.

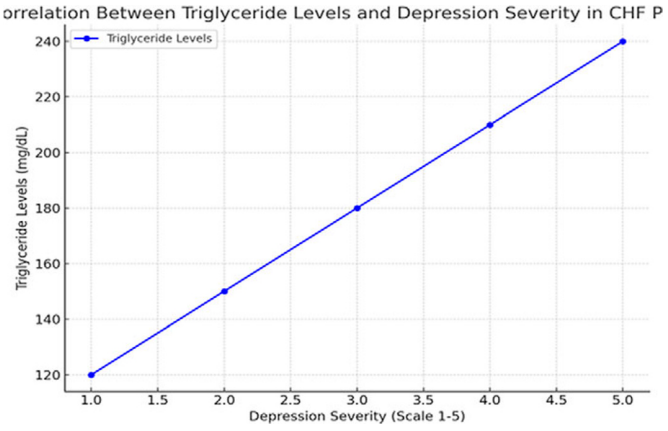
Depression in Patients with Chronic Heart Failure: Correlation with Hemodynamic Parameters and Lipids' Metabolism

S. Fedorov[1] and A. K. Sikora[2,3]*



[1]Therapy and Family Medicine department of Post-graduate Faculty; [2]Psychiatry, Addictions and Medical Psychology Department, Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine and [3]HOSPITAL OF THE MAZOWIECKIE VOIVODESHIP DREWNICA, Warsaw, Poland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.594

Introduction: Depression is a major concern in patients with chronic heart failure (CHF), with a prevalence of approximately 20-40%. It has been linked to worsened outcomes, including mortality and significant declines in physical and social functioning. Understanding the relationship between depression and hemodynamic as well as lipid metabolism parameters in CHF patients can provide insights into the underlying mechanisms of these worsened outcomes.
Objectives: This study aims to evaluate the correlation between depression and central hemodynamic and lipid metabolism parameters in patients with chronic heart failure (CHF).
Methods: The study involved 80 patients with CHF II-III NYHA classes caused by chronic coronary artery disease. They were divided into two groups: 20 without signs of depression and 60 with depression, as diagnosed using the Zung Self-Rating Depression Scale, Beck Depression Inventory, and Hamilton's Depression Scale. Hemodynamic parameters were assessed using echocardiography (EchoCG), and lipid levels were measured in blood plasma. Statistical analyses were performed using t-tests, Mann–Whitney U tests, and correlation coefficients to determine relationships between variables.
Results: Depressive symptoms were prevalent in 71.6% of the CHF patients, with severe depression observed in 3.3%. Significant correlations were found between depression severity and blood pressure, triglyceride levels ($r = 0.7$, $p < 0.05$), and key echocardiographic measures such as left atrium diameter ($r = 0.57$, $p < 0.05$), end-diastolic size ($r = 0.53$, $p < 0.05$), and ejection fraction ($r = -0.29$, $p < 0.05$). Additionally, situational anxiety was significantly correlated with serum urea levels ($r = 0.42$, $p < 0.05$), triglycerides ($r = 0.91$, $p < 0.05$), and echocardiographic parameters.

Image 1:

Parameter	Correlation Coefficient (r)	p-value	Interpretation
Systolic Blood Pressure (SBP)	-0.3	< 0.05	Moderate inverse correlation
Diastolic Blood Pressure (DBP)	-0.35	< 0.05	Moderate inverse correlation
Triglycerides (TG)	0.7	< 0.05	Strong direct correlation
Left Atrium Diameter (LA)	0.57	< 0.05	Moderate direct correlation
End-Diastolic Size (EDS)	0.53	< 0.05	Moderate direct correlation
Ejection Fraction (EF)	-0.29	< 0.05	Weak inverse correlation

Image 2:

Conclusions: Patients with CHF and depression exhibit more severe central hemodynamic and lipid metabolism disorders than those without depression. These findings suggest that addressing depression in CHF management may mitigate some of the adverse effects on cardiovascular health.

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.595

Introduction: The field of psychiatry is going through a rapid transformation as a result of the rapid advancements in artificial intelligence (AI), which are providing novel opportunities for the diagnosis, treatment, and management of mental health disorders. AI can deliver more precise and personalized mental health care by utilizing machine learning algorithms, natural language processing (NLP), and neuroimaging analysis. This paper investigates the current applications of AI in psychiatry, its prospective benefits, and the challenges that must be overcome in order to effectively integrate AI into clinical practice.

Objectives: To investigate contemporary advancements in artificial intelligence (AI) applications in psychiatry, emphasizing enhancements in diagnostic precision, therapeutic personalization, and ethical considerations for integration into clinical practice.

Methods: A thorough examination of AI applications in psychiatry was performed, encompassing AI utilization for psychiatric diagnosis, digital mental health therapies, neuroimaging analysis, and suicide risk assessment.

Results: Artificial intelligence demonstrated considerable potential in enhancing diagnostic precision, especially via technologies such as natural language processing for evaluating speech and text, and machine learning algorithms for assessing brain imaging. AI-driven chatbots and virtual therapists shown effectiveness in administering cognitive behavioral therapy (CBT) and facilitating continuous mental health care. Predictive algorithms for suicide risk and digital phenotyping instruments present opportunities for early intervention. Nonetheless, obstacles including algorithmic bias, data security issues, and the necessity for human oversight were identified as barriers to full implementation.

Conclusions: Artificial intelligence possesses revolutionary potential in psychiatry, facilitating earlier diagnoses, more individualized treatment strategies, and continuous monitoring of mental health disorders. For AI to be included into standard psychiatric care, continuous efforts are required to guarantee ethical implementation, mitigate algorithmic bias, and preserve the vital human connection in psychiatric therapy. Collaboration among AI engineers, physicians, and ethicists will be essential to fully leverage AI's potential while ensuring the safety of patients.

Evaluating Social Media as a source of Mental Health Information: Insights from Mental Health Practitioners

J. X. Chua[1], A. Alasiam[1*] and K. L. C. Ng[1]

[1]Department of Emergency and Crisis Care, Institute of Mental Health, Singapore, Singapore

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.596

Introduction: Social media has significantly changed the way we communicate, interact, and access mental health information for both the public and practitioners. Research indicates that rising rates of suicidal behaviors among adolescents may be linked to increased screen time on social media (Balt et al., 2023). Excessive use of online social networks can exacerbate self-harm and suicidal thoughts in vulnerable young people (Memon et al., 2018). Given Emergency Mental Health Professionals are most often in contact with suicidal patients, we developed a survey to gain a deeper understanding of their practices and attitudes toward social media platforms.

Objectives: We aim to explore social media usage patterns among mental health practitioners in Singapore's sole psychiatric emergency department, assess their views on the impact of social media as a mental health resource, and evaluate whether they believe suicide posts on social media should be treated with the same seriousness as traditional suicide notes.

Methods: The authors surveyed 58 mental health professionals - psychiatrists, nurses, psychologists, social workers, and pharmacists - who worked during 2023-2024. The survey, consisting of 19 multiple-choice questions, assessed attitudes toward mental health-related internet technologies and the perceived advantages and disadvantages of social media, based on a previous scientific paper titled "The Role of Social Media as a Resource for Mental Health Care". Responses were measured on a Likert scale (1 = Strongly Disagree to 5 = Strongly Agree). SPSS 16.0 was used to analyze correlations between demographics and attitudes toward social media as a mental health resource.

Results: Of the practitioners, 58.6% viewed social media's impact on mental health as negative. Notably, 32.4% of those with less than one year of experience held this view, compared to just 8.8% of those with 6 to 9 years of experience. A significant negative correlation was found between actively following mental health content on social media and the belief that social media increases suicide risk among vulnerable individuals ($P = 0.003$, $R = -0.389$). However, years of work experience did not significantly correlate with this belief ($P = 0.213$).

Conclusions: The study finds that while mental health professionals generally view social media negatively, those who engage with mental health content online are less likely to associate it with increased suicide risk. Our limited literature review found no similar studies, and we aim to provide new insights into how familiarity with mental health content influences professional attitudes. Expanding the research beyond Emergency Department practitioners could reveal how demographic factors shape opinions on social media.

A digitally supported guided self-help for depression and anxiety –The development and results of the Finnish guided self-help (F-GSH)

S. E. Saarni[1,2,3]*, K. Mikkonen[4], P. Roslund[5], S. Laitala[5] and S. I. Saarni[2]

[1]Psychiatry, HUS, Helsinki; [2]Psychiatry, University of Tampere, Tampere; [3]Päijät-Häme Well Being County, Lahti; [4]Helsinki University and [5]HUS, Helsinki, Finland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.597

Introduction: *Increasing access to short, evidence-based psychotherapies is essential for responding to the rapid increase of demand. This can be achieved only by implementing scalable digital solutions. The Finnish guided self-help (F-GSH) is a digitally supported treatment based on Cognitive Behavioral Therapy (CBT). It was implemented in 2020 onward as part of the national First Line Therapies initiative to face the increased demand and shortage of therapists in primary health care.*
Objectives: *We describe the implementation and preliminary results of the Finnish Guided Self-Help (F-GSH) of GSH for depression and anxiety in adults.*
Methods: *Description of the digitally supported F-GSH and therapist training using e-learning platform. We report preliminary outcomes from F-GSH for depression (n=766) and anxiety (n=1043). As outcomes we report self-reported depression (PHQ-9) and anxiety (GAD-7) symptoms measured at the beginning and end of the F-GSH treatment, patient and employee satisfaction, and proportion of patients in need of further treatment after F-GSH. Results are gathered from a wide geopraphical area covering 12 well-being counties.*
Results: *The training program includes a 5-7 hours online training. A multiple-choice exam must be passed at the end course to gain certification. The training can be enhanced locally by skills workshops, to refine abilities, discuss specific GSH programs and patient groups, or address local implementation issues. In August 2024 more than 2700 employees had undergone the F-GSH training. The symptom severity changes during the treatment in our sample were as follows: Depression program the mean PHQ-9 for depression were at the beginning and end of the treatment 15.4 (SD 5.4)- 11.2(6.0) and for anxiety symptoms GAD-7 10.3(4.7)-7.9(4.8). Respectively, for during the treatment program targeted for anxiety symptoms the GAD-7 levels were 12.25(4.8)- 8.8(5.0) and for PHQ-9 12.43(5.5)- 9.1 (5.6). Worsening of the symptoms were reported for 0-2% of the patients. Further treatment needed 38% of patients after F-GSH for depression and After F-GSH 38% of patients had no need for any further treatment.*
Conclusions: *E-learning platform forms a scalable and acceptable solution for training large number of professionals on a short time period at low cost for an evidence based treatment model. The symptoms reductions during the digitally supported F-GSH for depression and anxiety were comparable with previously reported in other studies, and comparable with longer CBT treatments. The F-GSH seems to be acceptable for the patients and employees. Also, the symptoms seem to ameliorate clinically significantly during the treatment.*

Attachment styles among Tunisian women: cross-sectional study

N. H. Benhamed[1]*, A. Hakiri[2], Y. Yaich[2] and B. Amamou[1]

[1]psychiatry department , EPS Fatouma Bourguiba , Monastir and [2]Psychiary B , Razi Hospital , Manouba, Tunisia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.598

Introduction: Attachment styles are essential for understanding how individuals form and maintain emotional connections and relationships, significantly influencing emotional well-being and interpersonal dynamics. In Tunisia, where cultural expectations around gender and relationships play a prominent role, exploring attachment styles provides insight into how women navigate intimacy, trust, and emotional security.
Objectives: This study aims to assess the prevalence of attachment styles among Tunisian women and investigate their associations with various sociodemographic and psychological factors
Methods: a cross-sectional study was conducted online using a Google Forms questionnaire between July and August 2024. The inclusion criteria were sexually active women aged 18 years or older who provided informed consent to participate. Participants completed a self-administered questionnaire that included sociodemographic information, personal medical history, lifestyle habits, and psychometric assessments. The relationship Questionaire (RQ) was used to evaluate attachement style and self-esteem was assessed using the Rosenberg Self-Esteem Scale (RSE).
Results: A total of 180 women participated in the study, with an average age of 32.79 years, ranging from 21 to 60 years. The majority, 97.78%, resided in urban areas, while 94.44% held a university degree, and 80% were employed. Medical history revealed that 21.11% reported organic issues, and 27.22% had a psychiatric history. Lifestyle habits indicated that 18.9% of women smoked, 21.1% consumed alcohol, and only 1.1% used psychoactive substances.
Evaluation of attachment styles showed that 57.78% of women exhibited a secure attachment style (n=104), 26.67% had an avoidant style (n=48), 8.89% displayed a disorganized style (n=16), and 6.67% had an anxious style (n=12). Attachment styles were significantly associated with age (p=0.003), employment status (p=0.004), marital status (p=0.01), organic health issues (p=0.02), history of suicide attempts (p<0.001), self-esteem (p<0.001), and the number of sexual partners (p=0.01).
Conclusions: The findings highlight that attachment styles are significantly linked to several sociodemographic and psychological factors among Tunisian women. Understanding these associations is crucial for developing targeted interventions that promote secure attachment patterns, improve emotional well-being, and enhance relationship quality. By addressing these dynamics, we can foster psychological resilience and support healthier relational patterns. Further research could extend these insights to broader sociocultural contexts, offering more tailored approaches to improving women's mental health and relational satisfaction.

Examining predictors of non-suicidal self-injury among college students: A prospective cohort study

J. N. Kjaer[1,2*] and B. Turner[3]

[1]Psychosis Research Unit, Aarhus University Hospital, Psychiatry; [2]Department of Clinical Medicine, Aarhus University, Aarhus, Denmark and [3]Department of Psychology, University of Victoria, Victoria, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.599

Introduction: Non-suicidal self-injury (NSSI) refers to the deliberate act physical harm without intent of suicide. Common forms of NSSI include cutting, burning, and hitting oneself. The prevalence of NSSI among college students have been estimated to be between 15% to 25%.and higher than in the general population. Investigating patterns associated neurobiological and personality traits may provide a more comprehensive understanding of NSSI.
Objectives: We aim to identify latent trajectory classes for NSSI behavior among college students. We expect that baseline personality and the behavioral inhibition/activation scales (BIS/BAS) will predict NSSI trajectory.
Methods: A total of 704 first-year university students at University of Victoria, Canada, were recruited in the beginning of the first semester over two consecutive academic years. Participants attended a baseline testing session completing self-report measures including the Ten Item Personality Inventory, BIS/BAS and NSSI instruments. There were monthly follow-up sessions from October to April. Longitudinal data will be analysed with latent growth curve modeling and group-based trajectory modeling, and baseline predictors will be analysed with multivariate logistic regression.
Results: Latent class growth analysis found three distinct classes of NSSI during the follow-up period. A small percentage (2.4%) of the participants had a high degree of self-injury throughout the follow-up period. A second class of 13.4% of the participants had a moderate degree of self-injury at baseline, which fell throughout the follow-up period. Lastly, a third class of the majority of the participants (84.3%) had minor or none self-injury both at baseline and in the follow-up period. Concerning baseline predictors, higher openness and BAS drive were associated with lower NSSI at baseline.
Conclusions: In line with previous studies, we identified three distinct trajectories of NSSI behavior among college students. Notably, low openness and low BAS drive were associated with a degree of NSSI at baseline. These findings suggest that openness and drive may play a protective role in NSSI, providing valuable insights for future prevention and intervention efforts. The project is part of the Collaborative Research Program at the International Society for the Study of Self-Injury.

Exploring the subjective role of diet for people living with severe mental illness: insights from a biopsychosocial perspective

A. S. Mueller-Stierlin[1*], R. Hiltensperger[1], S. Mörkl[2] and S. Teasdale[3]

[1]Institute for Epidemiology and Medical Biometry, University of Ulm, Ulm, Germany; [2]Klinische Abteilung für medizinische Psychologie, Psychosomatik und Psychotherapie, Medizinische Universität Graz, Graz, Austria and [3]University of New South Wales, Sydney, Australia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.601

Introduction: People living with severe mental illness (SMI) face a life expectancy reduction of 10 to 20 years, often due to physical comorbidities. In addition to medication side effects, unhealthy lifestyle choices may contribute to this disparity.
Objectives: Understanding the experiences and views of people living with SMI regarding diet is essential in addressing these challenges.
Methods: To explore the role of nutrition and its determinants within a biopsychosocial framework, 28 semi-structured interviews were conducted with service users living in Germany, Austria, and Australia. A generic thematic analysis was applied to uncover key themes around implications of dietary behavior and its determinants.
Results: Both positive and negative effects of diet were reported. A prominent theme was the mental strain related to body weight, which contributed to feelings of guilt and experiences of stigma. Numerous biological, psychological, and social factors were identified as influencing dietary choices and behaviors. Many participants expressed a desire for greater support in achieving dietary balance and breaking the vicious cycle between diet and mental health.
Conclusions: From the viewpoint of people living with SMI, dietary interventions should be more integrated into mental health care. Psychosocial aspects, such as the emotional impact of eating, are as important as biological factors like nutrient intake, emphasizing the need for a holistic approach to addressing diet in mental health care.

Prevalence and Risk Profile of Depression Among Adolescents in Rural and Indigenous Communities of Mexico: A Cross-Sectional Study

A. Vega[1,2*], L. Díaz-Castro[1], G. B. Ramírez-Rodríguez[3] and K. Hoffman[4]

[1]Direction of Epidemiological and Psychosocial Research, National Institute of Psychiatry Ramón de la Fuente Muñiz, Mexico City; [2]Neurogenesis Laboratory, National Institute of Psychiatry Ramón de la Fuente Muñiz, Ciudad de México; [3]Neurogenesis Laboratory, National Institute of Psychiatry Ramón de la Fuente Muñiz, Mexico City and [4]Research Center in Animal Reproduction, Autonomous University of Tlaxcala, Tlaxcala, Mexico
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.602

Introduction: Depressive disorders are the most prevalent chronic mental disorders globally, affecting approximately 322 million people, or 4.4% of the world's population, with a significant portion residing in the Americas, including Mexico. Adolescence represents a critical period for the onset of depression, where preventive interventions should focus on enhancing cognitive abilities, which are malleable and can mitigate the impact of early negative experiences, particularly in marginalized areas and indigenous communities.
Objectives: To identify the prevalence of depressive symptoms and characteristics associated with the presence or absence of depressive

symptoms in a population of adolescents and young adults residing in rural and indigenous communities in San Luis Potosi state, Mexico.
Methods: A cross-sectional study was conducted. Depressive symptoms were assessed using the Patient Health Questionnaire-9 (PHQ-9), while anxiety symptoms were measured using the Generalized Anxiety Disorder-7 (GAD-7) scale. Descriptive statistics, a comparative analysis and a principal components analysis were performed with the sociodemographic data and the evaluations of each item of the PHQ9 and GAD7.
Results: 1,057 participants aged between 15 and 25 years (16.63 ± 1.53 years) were included in the study. The sample comprised 60.51% females 39.48% males, and 7 participants reported speaking an indigenous language. 28.67% of participants had responses compatible with anxiety, while 34.98% had depression, of which 46.1% qualified as having major depressive disorder. Regarding GAD7, participants with higher severity scores presented a higher average response on item 3 about feeling excessively worried about different things, while those with depression did not respond predominantly to questions regarding mood, but rather to item 3 referring to having difficulty falling or staying asleep and item 4 about feeling tired or having low energy. 4.67% of participants reported suicidal ideation almost every day. When the GAD7 and PHQ9 items were subjected to a principal component analysis, it was observed that PC1=51.67%. The factors self-reported as most closely linked to depressive and anxious symptoms included the age of the caregiver, sex and age of the participant, as well as whether they spoke an indigenous language.
Conclusions: Difficulty falling and staying asleep, as well as perceived lack of energy or fatigue, are the main ways in which this population recognizes signs of depression, rather than feelings of sadness or anhedonia. Given the high prevalence of depressive symptoms and the identified risk profiles, there is an urgent need for targeted mental health services and interventions in these vulnerable populations.

Incidents of violence and proportionality of restrictive practices: a D-FOREST study

J. Leahy[1]*, B. Walls[1], A. Lindner[2], D. Duffy[1], P. McLaughlin[1], H. G. Kennedy[3] and M. Davoren[3]

[1]National Forensic Mental Health Service, Dublin, Ireland; [2]University of Mainz, Mainz, Germany and [3]Department of Psychiatry, Trinity College Dublin, Dublin, Ireland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.603

Introduction: Aggression and violence are common in psychiatric in-patient wards. Preventive measures such as de-escalation, increased observations, extra medication, restraint and seclusion are utilised by nurses and authorised by doctors in a highly skilled way that should be proportionate to the risks posed. There is limited empirical data on the proportionality of the use of restrictive practices within Irish forensic psychiatric units.
Objectives: The aim of this study was to rate the severity of incidents and proportionality of response to incidents in the high secure unit within the National Forensic Mental Health Service.
Methods: This is a prospective cohort study set in the Central Mental Hospital. Patients were assessed each day using the Dynamic Assessment of Situational Aggression (DASA) scale and incidents were rated each day using the DUNDRUM Restriction-Intrusion of Liberty Ladders Scales (DRILL), which includes the assessment of adverse incidents, violence and self-harm, interventions including restrictive practices and consequences. In this study we used episodes of restriction as an outcome measure. Data were gathered as part of the Dundrum Forensic Redevelopment Evaluation Study (D-FOREST). Generalised Estimating Equations were used to analyse repeated measures in the same subjects.
Results: There were 384 patient days in scope, 411 lines of data including 326 patient-days, 85 incidents and 63 incidents of seclusion. The DRILL scales had good internal consistency (DRILL behaviours scale Cronbach's alpha=0.789; DRILL interventions scale Alpha=0.866). The DASA on the day before an incident predicted the score on the DRILL behaviours scale (severity of behaviours) Wald X^2=39565.2, p<0.001, with DUNDRUM-1 triage security scale also contributing significantly to the model Wald X^2=884.3, p<0.001. The best model to predict the DRILL interventions scale included DASA on the day before (Wald X^2=14.6, p=0.012) DRILL-behaviours scale (Wald X^2=728.7, p<0.001) and DUNDRUM-1 (Wald X^2=10,819.4, p<0.001). This was also the best model to predict whether or not a patient was secluded (DASA day before Wald X^2=46.4, p<0.001; DRILL-behaviours scale Wald X^2=173.2, p<0.001; DUNDRUM-1 Wald X^2=6153.5, p<0.001).
Conclusions: Harmful behaviours and preventive and restrictive interventions can be described by rating items ('ladders') with good internal consistency, demonstrating that behaviour escalates in a meaningful sequence of increasingly serious harmful occurrences. The more serious the incident, the higher the level of restrictive practice used, demonstrating proportionality. This model of short term risk assessment and preventative interventions can be used to develop more effective and less restrictive interventions. Future research will explore moderating and mediating factors.

The application value of facial expression analysis system in violence risk assessment of patients with mental disorders

X. Ling[1,2]*, S. Wang[1], X. Zhou[3], N. Li[4], W. Cai[1] and H. Li[1]

[1]Shanghai Key Lab of Forensic Medicine, Key Lab of Forensic Science, Ministry of Justice, Shanghai Forensic Service Platform, Academy of Forensic Science; [2]Department of Forensic Medicine, School of Basic Medical Sciences, Fudan University; [3]The Smart Medicine and AI-based Radiology Technology Lab, School of Communication and Information Engineering, Shanghai University and [4]Shanghai Hongkou Mental Health Center, Mental Health Center Affiliated to Shanghai University School of Medicine, Shanghai, China
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.604

Introduction: Patients with mental disorders often engage in extreme and unpredictable violent behaviors that seriously endanger the public security and stability of the society. Violence risk is commonly assessed by subjective judgement, which may lead to bias and uncertainty in the appraisal results. Existing expression recognition and analysis techniques have limitations in identifying the emotional states of patients with mental disorders.
Objectives: The study aimed to explore the association between violent behaviors and facial expression in patients with mental disorders by machine learning algorithm, to evaluate the application value of facial expression analysis system in violence risk assessment of individuals with mental disorders.
Methods: Thirty-nine patients with mental disorders were enrolled and assessed by using Modified Overt Aggression Scale (MOAS), positive and negative syndrome scale (PANSS) and brief psychiatric rating scale (BPRS). An emotional arousal paradigm was performed and the intensity of baisc emotions and expression action units was recorded before, during and after the paradigm. The processed quantitative data was used to generate one-dimensional waveform maps and two-dimensional time-frequency maps and then quantized feature data were extracted. A machine learning model with high accuracy was trained using these feature data, which can accurately determine the violence risk states of patients and output the probability. All individuals participated voluntarily and provided informed consent. This study was approved by the ethics committee of the Academy of Forensic Science.
Results: The intensity difference of sadness, surprise and fear in different time periods was statistically significant. The intensity of the left medial eyebrow lift action unit was found significantly different before and after the emotional arousal. The intensity of anger and disgust was positively correlated with the MOAS scores, PANSS scores and BPRS scores. The features of time-frequency diagrams of 5 expression action units (medial eyebrow raise, eyebrow lowering, slightly open lips, chin drop and eye closure) and 8 basic emotions were selected and then support vector machine was used for triple classification, which is a classifier that can well distinguish the three stages of non-violence risk period, violence risk period, and post-violence risk period. In the 4:1 training-testing grouping, the classification accuracy reaches 91.2%.
Conclusions: Featured expressive action units and various baisc emotions might be used to capture information associated with violent behaviors. The facial expression analysis system mentioned above can be used as an auxiliary tool to assess the potential risk of violence in patients with mental disorders.

Transforming Psychiatric Emergency Care: A Community-Focused Model in Trento, Italy

W. A. R. Di Napoli[1], D. Scordato[1]*, F. Fasoli[1], N. Benedetti[1] and C. Agostini[1]

[1]Trento Mental Health Center, Azienda Provinciale per i Servizi Sanitari - Trento, Trento, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.605

Introduction: Psychiatric emergencies are a global challenge requiring timely, effective interventions. Traditional intra-hospital approaches often struggle to address the complexity of these crises in a patient-centered and family-inclusive manner. Trento's Mental Health Service has implemented a community-based, multidisciplinary approach to manage psychiatric emergencies, emphasizing the socio-familial context of each crisis.
Objectives: This study aims to evaluate the effectiveness of the Trento Crisis Team in managing psychiatric emergencies outside of hospital settings, reducing hospital admissions, and enhancing patient and family engagement in the recovery process. Additionally, we assess the impact of the crisis service on public stigma related to mental health crises.
Methods: The study reviews the structure and organization of the Trento Crisis Team, which operates within the Mental Health Centre. The team includes 3 psychiatrists, 5 nurses, 5 educators/psychiatric rehabilitation technicians (TERP), and 5 Peer Support Specialists (*"ESP"* in Italian). Data were collected from emergency intervention records, hospital admission rates, and user satisfaction surveys. Comparisons were made between territorial and intra-hospital crisis management outcomes, with statistical analysis on key performance indicators such as the number of hospital admissions and compulsory health treatments.
Results: Preliminary results indicate a reduction in hospital admissions (*Image 1*) and a significant decrease in the number of compulsory interventions (*Image 2*) since the establishment of the dedicated Crisis Team. While overall user numbers have increased (*Image 3*), the availability of peer support and home-based interventions has improved patient satisfaction and engagement. However, the system still faces challenges in reducing hospital admissions due to the increasing volume of psychiatric emergency cases.
Image 1:

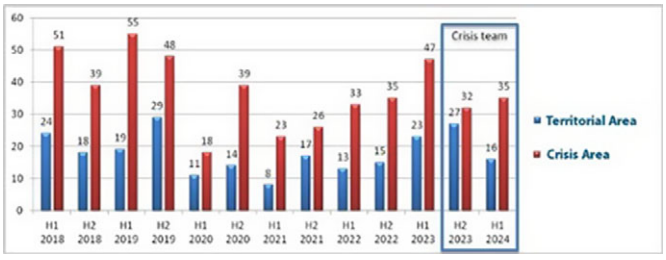

Image 2:

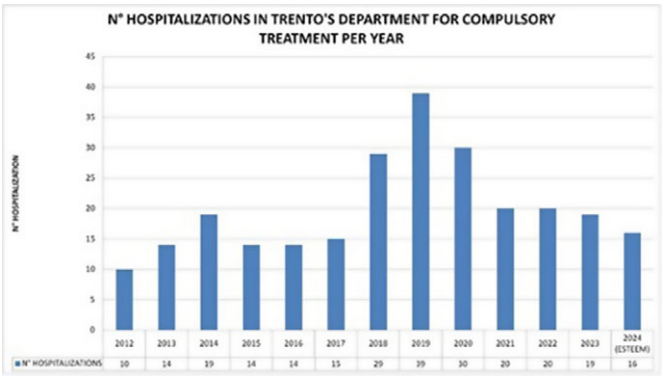

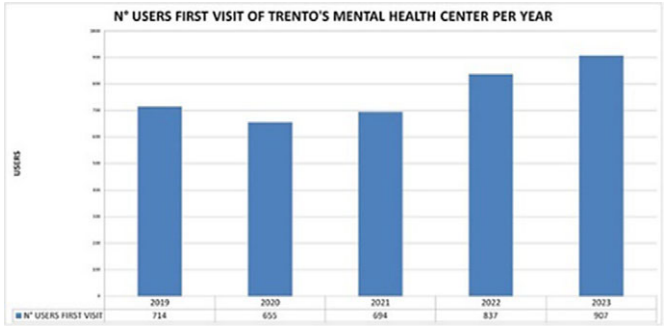

Image 3:

Conclusions: The community-based crisis management model adopted by the Trento Crisis Team offers a promising alternative to traditional hospital-based interventions. By focusing on the individual's socio-familial environment and engaging Peer Support Specialists, the service has demonstrated a capacity to humanize mental health crises and reduce public stigma. Continued efforts are necessary to address resource constraints and further integrate crisis management into community mental health pathways.

The application of traffic psychology scales in assessment for fitness-to-drive of individuals with mental disorders

S. Wang[1]*, X. Ling[1], Q. Zhang[1] and H. Li[1]

[1]Shanghai Key Lab of Forensic Medicine, Key Lab of Forensic Science, Ministry of Justice, Shanghai Forensic Service Platform, Academy of Forensic Science, Shanghai, China

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.606

Introduction: Mental disorder may affect individual's ability to operate the motor vehicle. Previous studies have found that patient's negative emotions may trigger aggressive driving behaviors. Thus, efficiently evaluating the correlation between emotions and driving behaviors in individuals with mental disorders has been drawn emphasis.

Objectives: To explore the related factors of fitness-to-drive of individuals with mental disorders, to determine the application value of traffic psychology scales in assessment for fitness-to-drive of individuals with mental disorders, and to help establish consummate and effective assessment systems.

Methods: One hundred individuals with mental disorders were enrolled as the patient group, and 100 healthy individuals were enrolled as the control group. Positive and Negative Syndrome Scale (PANSS) was used to assess the psychiatric symptoms of the patient group. Driver Profile of Mood States (DPOMS), Driver Anger Scale (DAS), and Driving Behavior Scale (DBS) were used to evaluate the performance during driving within two groups. T-test were used to compare the differences in each factor score of traffic psychology scales within two groups. Pearson's correlation analysis was used to calculate the correlation between scores of PANSS and scores of traffic psychology scales of the patient group.

Results: The patient group had significantly higher score of driving function deficit in DBS than the control group ($t=2.48$, $P<0.05$), but scores of hostile gestures, impolite driving, overly cautious behaviors in DBS and total score of DAS showed the opposite ($P<0.05$). Positive syndrome in PANSS was positively related to traffic congestion in DAS ($r = 0.315$, $P < 0.05$). Anger in DPOMS was positively related to driving function deficit ($r = 0.488$, $P < 0.01$) and hostile behaviors in DBS ($r = 0.510$, $P < 0.01$), whereas it was negatively related to overly cautious behaviors in DBS ($r = -0.417$, $P < 0.05$). Anxiety and depression were also related to some factors in DAS and DBS.

Conclusions: The study found the practical application value of DPOMS, DAS, and DBS in assessment for fitness-to-drive of individuals with mental disorders. Patient's anger in specific traffic situations such as traffic congestion may be mainly related to their positive syndrome. Patient's anger may be a trigger of aggressive driving behaviors, and other emotions such as anxiety and depression also play important roles. Patient's aggressive driving behaviors may be attributed to the compounding of many negative emotions.

Evaluation of Mitochondrial DNA (mtDNA) Copy Number Alterations and Clinical Parameter Correlations in Patients with Methamphetamine Use Disorder

H. M. Aytac[1,2*], Y. Oyaci[1,3], M. Pehlivan[4], S. I. Azizoglu[2], O. Guclu[2] and S. Pehlivan[1,3]

[1]Institute of Graduate Studies in Health Sciences, Istanbul University; [2]Department of Psychiatry, Basaksehir Cam and Sakura City Hospital, University of Health Sciences; [3]Department of Medical Biology, Istanbul Faculty of Medicine, Istanbul University and [4]Department of Hematology, Basaksehir Cam and Sakura City Hospital, University of Health Sciences, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.607

Introduction: Methamphetamine use disorder (MUD) and associated conditions impose a significant burden not only on affected individuals and their families but also on communities. Neurotransmitter system imbalances, mitochondrial dysfunction, oxidative stress, and activation of the inflammasome have all been implicated in methamphetamine-induced neurotoxicity. However, whether MUD is associated with peripheral mtDNA alterations remains uncertain.
Objectives: This study aimed to investigate the relationship between mtDNA copy number and clinical parameters in individuals diagnosed with MUD, comparing them with healthy controls.
Methods: Our study is a case-control research involving 52 patients diagnosed with MUD based on DSM-5 criteria and 52 healthy controls. Peripheral blood samples were collected, and leukocytes were isolated using the ELK Biotech Genomic DNA Extraction Kit for genomic DNA extraction. DNA samples were diluted to a concentration of 0.5-2 ng/µl for mtDNA copy number analysis, which was performed using the ScienCell qPCR Assay Kit. Two qPCR reactions were carried out for each sample using mtDNA and SCR primer sets. Known mtDNA copy number samples were used as references, and mtDNA copy numbers for each sample were calculated using the comparative $^{\Delta\Delta}$Cq method.
Results: When comparing the mtDNA copy numbers between patients diagnosed with MUD and the control group, the mtDNA copy number in individuals with MUD was found to be significantly lower than that of the control group (p=.001). After controlling for age and gender, clinical parameters (suicide attempt, non-suicidal self-injury, duration of disorder, withdrawal symptoms, psychosis) and scale scores were compared based on mtDNA copy numbers. Among these, only substance use duration showed a statistically significant difference between the groups (p=.045). Additionally, in this study, a significant negative correlation was found between mtDNA copy numbers and the duration of disorder in MUD patients (r=-.369, p=.008).
Conclusions: This is the first study examining the relationship between peripheral mtDNA alterations and clinical parameters in individuals diagnosed with MUD. A previous study showed that individuals with MUD exhibited decreased mtDNA copy numbers and increased mtDNA damage compared to healthy individuals in the Chinese population. Consistent with these findings, it was suggested that methamphetamine could lead to mitochondrial dysfunction and a reduction in mtDNA copy numbers in cell lines and animal models. In conclusion, individuals with MUD show decreased mtDNA copy numbers in peripheral blood samples, potentially related to increased autophagy. In this context, the reduction in mtDNA copy numbers could be used as a biomarker for MUD, and preventing this reduction may be beneficial in the clinical treatment of addiction.

Polygenic risk score for autoimmune disorder SLE predicts current depression but independently of exposure to recent stress

A. Berezvai[1], D. Torok[1,2,3], S. Krause[1,4], G. Bagdy[1,2], G. Juhasz[1,2] and X. Gonda[2,5*]

[1]Department of Pharmacodynamics, Faculty of Pharmacy; [2]NAP3.0-SE Neuropsychopharmacology Research Group, Hungarian Brain Research Program; [3]Doctoral College, Pharmaceutical Sciences and Health Technologies Division; [4]Doctoral College, Mental Health Sciences Division and [5]Department of Psychiatry and Psychotherapy, Semmelweis University, Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.608

Introduction: Inflammation has emerged in recent year as one potential contributor pathway in the background of several neuropsychiatric disorders, including depression. It is also increasingly understood that inflammation may exert its role via mediating the effect of stress in the etiology of such conditions. Therefore, understanding the role of inflammation in the background of depression would offer novel insight into the involved processes facilitating the identification of related biomarkers, novel treatment targets, as well as possibilities for early screening, risk identification, and prevention and intervention. In spite of these promising possibilities, currently we know little about the shared genetic risk in case of autoimmune or inflammatory conditions and depression.
Objectives: Our present analyses aimed at investigating, using polygenic risk scores, if genetic predisposition to inflammatory or autoimmune disorders predicts depression scores and if recent exposure to life stressors interacts with the effect of genetic variation.
Methods: For establishing polygenic risk scores (PRS) for different inflammatory/autoimmune conditions, we pre-existing GWAS summary statistics were used for systemic lupus erythematosus (SLE) (7219 cases, 15991 controls), autoimmune thyroid disease (AT) (859 cases, 324074 controls), and atrophic gastritis (AG) (180 cases, 456168 controls). The NewMood database (N=1820) was used as target data. Brief Symptom Inventory Depression Scale scores reflecting current depressive symptom severity was used as outcome depression phenotype. PRS calculations were performed with LDpred2. Linear regression models performed with R (4.1.3) were used to investigate the main effect of the PRS and the interacting effect of recent stress and PRS on current depression score.
Results: The main effect analyses showed that SLE-PRS had a significant effect on depression (beta=0.2389, p=0.0175) while AT-PRS (beta=0.4094, p=0.9763) and AG-PRS (beta=0.4741, p=0.5795) did not show significant main effects. Interaction analyses did not show significant effect in case of any of the examined autoimmune/inflammatory disorders (SLE-PRS x recent stress:

beta=0.1041, p=0.2016; AT-PRS x recent stress: beta=19.82, p=0.05811; AG-PRS x recent stress: beta=0.3169, p=0.6661).
Conclusions: Our present results show that while there is an overlap in the genetic background of depression and some autoimmune or inflammatory conditions, current stressors may not have an interacting role in this relationship. Our results need replication in larger samples, and should be extended to investigate polygenic scores for other conditions and other types of stress.

COX-2 gene rs689466 polymorphism and nicotine dependence among schizophrenia patients

S. Nadalin[1,2*], M. Vilibić[2,3], V. Peitl[2,3], A. Silić[2,3], I. Ljoka[3], I. Majdandžić[4], P. Posavec[5], D. Karlović[2,3] and A. Buretić-Tomljanović[6]

[1]Department of Psychiatry, General Hospital "Dr. Josip Benčević", Slavonski Brod; [2]School of Medicine, Catholic University of Croatia; [3]Department of Psychiatry, Sestre Milosrdnice University Hospital Center, Zagreb; [4]Department of Anesthesiology, Reanimatology and Intensive Care Medicine, General Hospital "Dr. Josip Benčević", Slavonski Brod; [5]Faculty of Health Studies, University of Rijeka and [6]Department of Medical Biology and Genetics, Faculty of Medicine, University of Rijeka, Rijeka, Croatia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.609

Introduction: In addition to play a key role in the generation of the inflammatory response, cyclooxygenases (COXs) are involved in a variety of other physiological processes, including dopaminergic signaling, and the skin flush response to the water-soluble B vitamin niacin. Patients with schizophrenia frequently exhibit abnormal signaling of dopamine and other neurotransmitters and attenuated niacin skin flush response. Clinical studies reported beneficial effects of selective cyclooxygenase-2 (COX-2) inhibitors on the simptom expression of schizophrenia, as measured by the Positive and Negative Syndrome Scale (PANSS). Several studies investigated potential correlations between functional rs689466 polymorphism (A/G polymorphism) of the COX-2 gene and etiology of schizophrenia, but the results have not been consistent. While we did not find evidence that the COX-2 polymorphism was associated with an elevated risk of schizophrenia risk in a Croatian population, we observed that the COX-2 polymorphism contributes to attenuated niacin skin flushing in patients with schizophrenia.
Objectives: To the best of our knowledge, no studies have investigated the potential associations between any COX-2 gene polymorphisms and the etiology of nicotine dependence. Based on the elevated smoking rate observed consistently in patients with schizophrenia and the possible relevance of COX-2 genes in schizophrenia and nicotine dependence via dopaminergic signaling, we investigated whether the risk of nicotine dependence among patients with schizophrenia is associated with the COX-2 gene rs689466 polymorphism. Given evidence suggesting that smoking influences the severity of schizophrenia, we also hypothesized that an interaction between smoking and the COX-2 polymorphism may contribute to the age of schizophrenia onset and/or PANSS psychopathology.
Methods: Polymerase chain reaction analysis/restriction fragment length polymorphism analysis was used to genotype 190 chronically ill schizophrenia patients treated with antipsychotic medications (104 males/86 females).
Results: There were no significant differences in the distribution of COX-2 genotypes and alleles in male or female schizophrenia patients who were stratified based on their smoking status and no COX-2 genotype-smoking interaction on PANSS psychopathology ($P > 0.05$). We revealed a significant COX-2 genotype-smoking interaction on the time of disease onset among female patients ($P < 0.05$). An earlier onset, observed for female smokers carrying the G-allele in their COX-2 genotypes (COX-2-GG homozygous and COX-2-AG heterozygous), in comparison to nonsmoking COX-2-G allele carriers, contributed mostly to this finding.
Conclusions: Our results indicate no COX-2 gene polymorphism's effect on the risk of nicotine dependence, but they suggest that COX-2 genotype-smoking interaction might be of relevance in disease onset, in a gender-specific fashion.

Quantitative Co-expression and Pathway Analysis Reveal the Shared Biology of Intellectual Disabilities

J.-A. Sharif[1*], J. Timmons[1] and P. Chapple[1]

[1]Queen Mary University of London, William Harvey Research Institute, London, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.610

Introduction: Intellectual disabilities(ID) are heterogeneous conditions, where mutations in more than 1000 genes are associated with ID. In the Genomic England gene panel, at least 1399 genes have sufficient evidence to be deemed diagnostic grade. The cellular pathways in some of these genes function remain ill-defined.
Objectives: Identification of molecular pathways or upstream regulators common across multiple intellectual disability genes would increase our understanding of the pathophysiological mechanisms and potentially identify therapeutic targets. Quantitative network analysis, using large datasets, is a potentially robust way to identify functional pathways, yet it has not been applied to ID genes at scale.
Methods: We have used co-expression analysis to identify functional modules of genes co-expressed with 1399 causative ID gene in human brain tissues. Specifically, we optimised existing large-scale transcriptomic data from three separate human brain data sets (>1,000 samples), one of which is neocortex (Kang *et al.* Nature 2011; 478 483–489, Trabzuni *et al. Nat Commun*2013; 4, 2771). Optimisation included reannotation, signal filtering, data scaling and then application of Multiscale Embedded Gene Co-expression Network Analysis (MEGENA) framework (Song W-M, Zhang B PLoS Comput Biol 2015; 11 11), to define robust network structures. Gene ontology was carried out using Metascape (Zhou Y *et al.* Nat Commun. 2019 Apr 3;10(1):1523).
Results: Following validation steps, we have confirmed our strategy produced valid co-expression modules for genes with known biology. For example, OXPHOS genes were detected in the same module (Image 1). Moreover, for modules containing ID genes,

that have been extensively studied, ontology analysis of the module identified terms related to their known function. A sunburst plot was generated to map intellectual disability genes against co-expression modules (Image 2). The most ID gene enriched neocortex module underwent gene ontology (Image 3) consisting of twelve ID genes, gene ontology was consistent with neuronal cell biology including "trans-synaptic signaling" and "brain development".

Image 1:

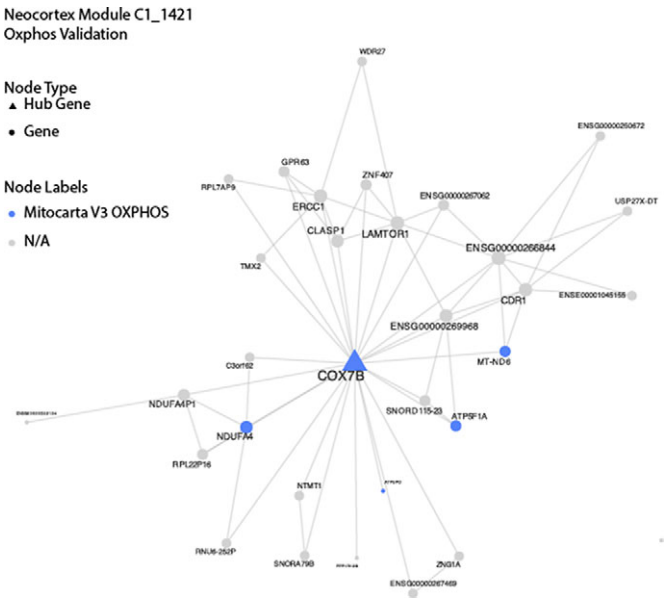

Image 3:

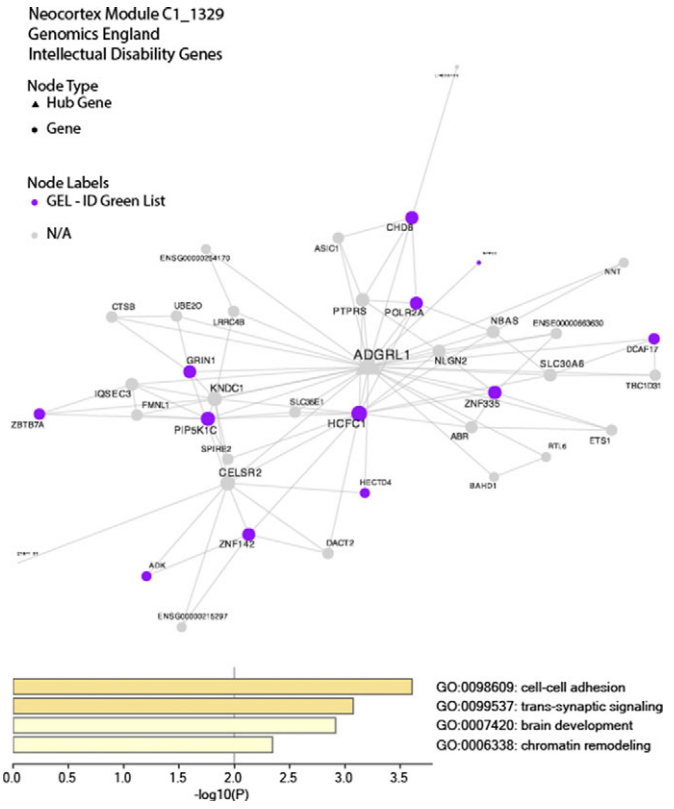

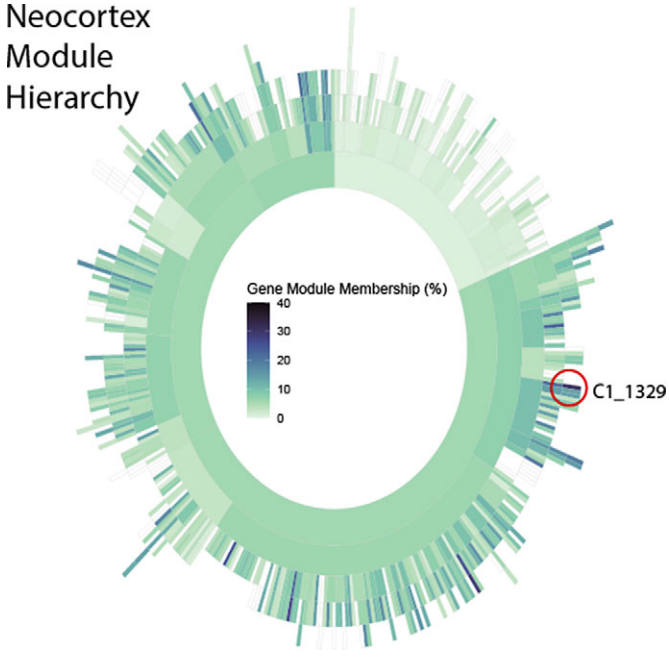

Image 2:

Conclusions: We have identified functional modules of genes that co-expressed with causative ID genes in human brain. The genes HCFC1, ZNF355, GRIN1, POLR2A and PIP5K1C in neocortex module C1_1329 are associated with microcephaly and ID (Koufaris C *et al.*Biomed Rep. 2016, Stouffs K *et al.* Clin Genet. 2018;, Platzer K *et al.* GeneReviews 2019, Haijes HA *et al.* Am J Hum Genet. 2019, Morleo M *et al.* Am J Hum Genet. 2023). Defining ID gene co-expression modules provided new insights into their underlying biology, revealing novel molecular links between different intellectual disability genes. This should improve molecular classification of these diseases as well as highlight therapeutic targets, facilitating drugs discovery and repositioning for rare causes of intellectual disabilities.

Extreme temperature and mood disorders: A systematic review of literature

N. Manoj[1,2*], M. K. Kennedy[1], M. Liu[1] and A. T. Olagunju[2,3,4,5]
[1]Michael G. DeGroote School of Medicine; [2]Department of Psychiatry and Behavioural Neurosciences, McMaster University; [3]Forensic Psychiatry Program, St. Joseph's Healthcare Hamilton, Hamilton, Canada; [4]Department of Psychiatry and Behavioral Sciences, University of Oklahoma, Oklahoma City, United States and [5]Discipline of Psychiatry, The University of Adelaide, Adelaide, Australia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.611

Introduction: The prevalence of extreme temperature is increasing largely due to the progression of climate change globally (LaSorte *et al.* Climate Change 2021; 166 1-2). Existing research indicates extreme temperatures have an impact on mental health, including its effect on mood disorders (Rony & Alamgir. Health Sci Rep 2023; 6 12). While there is evidence to suggest that mood disorders can be influenced by various environmental, biological, and social factors (Zhang *et al.* Environmental International 2020; 143), no study has synthesized findings on the relationship between extreme temperature and mood disorders in existing literature.
Objectives: The study aims to: investigate the linkage between extreme temperature and mood disorders in terms of symptom severity, hospital admissions and adverse events; describe factors moderating the relationship between extreme temperature and mood disorders; outline study-defined interventions and make policy recommendations.
Methods: This review was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guideline. Major databases (Medline/PubMed, PsychINFO, Scopus, Web of Science) were searched for eligible reports using a search strategy developed for the study. This was supplemented by snowball searching for references in relevant studies. Title and abstract screening and data extraction were completed by at least two independent investigators and conflicts were resolved by discussion amongst investigators or consulting the senior author. All included studies will be assessed with the National Institutes of Health Study Quality Assessment Tools.
Results: As seen in Image 1, 468 articles were identified from searching databases. Following screening and full-text review, 22 articles were selected for data extraction. Preliminary findings showed that the included studies were conducted in North America, Europe, Asia, and Oceania-Australia among others. The included studies were of different designs, including case-crossover, cohort and cross-sectional studies. Findings across studies indicate that extreme temperatures have a complex and significant impact on mood disorders. High temperatures were associated with increased hospital admissions, with adolescents, women, and the elderly especially vulnerable. Individuals with bipolar disorder and depression showed increased sensitivity to heat exposure. While some studies found increased emergency department visits for mood disorders during periods of extreme heat, others revealed insignificant correlations. Moreover, short-term exposure to humidity was also linked to elevated risk for mood disorders.

Image 1:

Conclusions: This study underscores the impact of extreme temperatures on mood disorders and highlights the need for real-world solutions, like policy implementation, to reduce exposure to such conditions due to climate change.

Unveiling the Psychological Impact of Climate Change: Generational Differences of Eco-Anxiety Among Italian Blood Donors

F. Marcolini[1*], J. K. Rocholl[1], S. Tempia Valenta[1], D. De Ronchi[1] and A. R. Atti[1]
[1]Department of Biomedical and Neuromotor Sciences , University of Bologna, Bologna, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.612
Introduction: Climate change is a pressing issue with significant impacts on both physical and mental health. Beyond threats to basic needs (e.g., water, clean air, food, and stable housing) and trauma from extreme weather events, its broader psychological effects, such as eco-anxiety, are gaining recognition. The American Psychological Association defines eco-anxiety as "a chronic fear of environmental doom," which can lead to cognitive, emotional, and functional decline, along with somatic symptoms. Despite its growing recognition, climate

change-related anxiety is still an emerging concept. In Italy, studies on eco-anxiety are limited but necessary, as the country is identified by the Intergovernmental Panel on Climate Change (IPCC) as particularly sensitive to climate change.
Objectives: The aim of this study is to assess the prevalence of eco-anxiety in a population of Italian blood donors, with a particular focus on its distribution across different generational cohorts.
Methods: An online questionnaire, structured on the Qualtrics platform, was administered via QR code among blood donors affiliated with AVIS (Associazione Volontari Italiani Sangue) in Bologna, Italy, in May 2024. Demographic and social data were collected, and the HEAS questionnaire was used to assess eco-anxiety.
Results: The study included 1,795 participants (1,060 males, 727 females, 8 non-binary) with an average age of 46.6 years (range 18-70). The results revealed variation in the detection of eco-anxiety among participants (mean HEAS score: 5.09; SD: 5.84). Analyzing differences in the presence of eco-anxiety across various age groups, the mean HEAS score was found to be higher in the GenZ group, defined as those aged 18-28 years (mean: 8.65; SD: 7.50), compared to other groups. Kruskal-Wallis analyses confirmed statistically significant differences in the presence of eco-anxiety across generations (p-value < 0.001). The data indicate that, in the GenZ sample considered, the prevalence of eco-anxiety is 48.4%, representing nearly five out of ten young individuals (chi-square value: 81.3; p < 0.001). Spearman's correlation and univariate logistic regression confirm the statistical validity of the association between generation and anxiety experiences related to climate change.
Conclusions: The data highlight the alarming spread of eco-anxiety in contemporary society, particularly among younger generations. Given the significant consequences, it is crucial to deepen our understanding of this condition and its psychosocial determinants.

Breaking the Silence: Exploring Self-experienced Discrimination Among Non-EU Physicians in Denmark

F. Monshizadeh Tehrani[1]*, M. Nouri[2], M. Hossein Pour[3], V. H. Santos[4,5] and D. Zani[6,7]

[1]Child and Adolescents Mental Health Center, Mental Health Services in the Capital Region of Denmark, Copenhagen, Denmark; [2]Zanjan University of Medical Science, Zanjan, Iran, Islamic Republic Of; [3]Pilehuset Dementia Center, Municipality of Copenhagen, Copenhagen, Denmark; [4]Department of Psychiatry and Mental Health, Cova da Beira Local Health Unit; [5]Faculty of Health Sciences, University of Beira Interior, Covilhã, Portugal; [6]Psychiatric Services Grisons, Chur and [7]Institute for Biomedical Ethics and History of Medicine, University of Zurich, Zurich, Switzerland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.613

Introduction: Discrimination against foreign healthcare professionals is an underexplored issue. Like many other countries, Denmark is experiencing an increasing influx of non-European Union (EU) physicians. These physicians face higher levels of requirements to obtain authorization to practice and be included in the Danish healthcare sector compared with their European peers, which can lead to an experience of perceived discrimination. Considering importance of physicians' mental health, addressing this perceived discrimination is crucial.
Objectives: This study aims to evaluate the perceived daily discrimination among non-EU physicians residing in Denmark. We focus on those who have immigrated within the past 10 years to shed light on the challenges faced during their integration into the Danish healthcare system.
Methods: 62 non-EU physicians who immigrated to Denmark within the last decade participated in the online survey during January 2024. The survey consisted of demographic information and Perceived Discrimination Scale (PDS). PDS was used to assess daily discrimination. Participants were grouped based on their duration of stay in Denmark and employment status. A Kruskal-Wallis H Test was conducted to compare the median daily discrimination scores across the different groups, using SPSS version 29.
Results: The study revealed that 74% of the participants who had lived in Denmark for less than four years were unemployed (p-value=0.001), suggesting significant challenges in finding employment. Furthermore, participants living in Denmark for over four years reported significantly higher levels of perceived daily discrimination compared to newcomers (p-value=0.016), indicating difficulties in integration. Similarly, employed physicians, reported higher discrimination levels than their unemployed peers (p=0.053), suggesting discrimination experiences at work.
Conclusions: This study reveals that non-EU physicians in Denmark face significant challenges to secure employment, especially in their first years of residence. Additionally, perceived discrimination for the physicians may be influenced by both employment status and duration of stay. High unemployment rates among recent arrivals and increased discrimination for those residing longer suggest that extended integration into the Danish healthcare system can intensify feelings of bias.

Sartre's Existential Psychopathology: The Role of Freedom and Personal History in Mental Health

F. Cunha[1]*, I. Santos[1], N. Castro[1], R. Andrade[1] and S. Borges[1]

[1]ULS Viseu Dão-Lafões, Viseu, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.614

Introduction: The existentialist approach to psychopathology emphasizes the need to understand the conditions that allow for the emergence of psychological disorders, referred to as "conditions of psychopathologization." This perspective, rooted in phenomenological methodology, rejects deterministic biomedical models, favoring a holistic view that considers the subject's lived experience, freedom, and choice. Drawing on the work of Jean-Paul Sartre, this study aims to analyze how existential conditions such as past events, personal choices, and social contexts contribute to the development of psychopathological states.

Objectives: The primary objective of this research is to explore the existentialist understanding of psychopathology, particularly focusing on Sartre's contributions to making psychopathological experiences comprehensible.
Methods: Narrative review of relevant literature.
Results: The findings highlight that psychopathological conditions often arise when individuals are alienated from their own projects of being. These conditions are shaped by personal histories, societal structures, and choices made in "bad faith" (self-deception). Past events, such as family dynamics, social oppression, and traumatic experiences, play a critical role in shaping the individual's choices and actions. Sartre argues that when individuals distance themselves from their authentic desires and intentions they experience existential alienation, which manifests as psychopathology. A key result is the understanding that psychopathology should not be seen as a mere malfunction of the brain, as suggested by the biomedical model. Rather, it is a comprehensible event in the subject's individual and social history. The deviation from an authentic life project is central to understanding the origin of psychological disorders.
Conclusions: Sartre's existentialist framework offers significant contributions to the field of psychopathology by making psychological suffering comprehensible through the lens of personal freedom and choice. The rejection of a purely biomedical or deterministic approach allows for a more nuanced understanding of the individual's psychological struggles as part of their broader life context. Psychopathology is thus seen as a breakdown in the relationship between the subject's life project and their historical or existential situation, where the individual either chooses to distance themselves from their authentic self or is forced to do so by external contingencies. Sartre advocates for a "reciprocal" clinical relationship that recognizes the patient's subjectivity, transforming the clinical space into one of genuine listening and understanding. This existentialist clinical model focuses on the subject-in-situation.

Transdiagnostic investigation of schizophrenia and autism spectrum: Heart rate variability changes during rest, relaxation, and cognitive tasks

F. Kinga[1]*, Á. Vass[1], Z. Pálffy[2] and G. Csukly[1]

[1]Department of Psychiatry and Psychotherapy, Semmelweis University and [2]Department of Cognitive Science, Budapest University of Technology and Economics, Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.615

Introduction: Autism spectrum disorder (ASD) and schizophrenia (SCH) are distinct diagnoses. However, they share common features such as high heritability, neurodevelopmental origins, and difficulties in social communication. Despite this, the etiology and precise pathophysiology of both conditions remain unclear, and no biomarker can definitively distinguish between them. In addition to higher-level cognitive and social-communication skills, autonomic regulation capacity is crucial for emotional regulation in social situations, which has been shown to differ in ASD and SCH according to the literature.
Objectives: Our study, part of a larger research project, aimed to explore autonomic regulation in ASD and SCH by investigating heart rate (HR) and heart rate variability (HRV) as key markers of autonomic nervous system functioning. We measured these parameters during rest, relaxation (body scan), and cognitive tasks to assess changes in autonomic regulation capacity across different conditions.
Methods: Participants underwent an electrocardiogram (ECG) recording during a longer EEG experiment. We analyzed heart rate and HRV data from 114 participants (N_{ASD}= 38, N_{SCH}= 37, and N_{NTP}= 39), with a particular focus on the RMSSD parameter as a key marker of parasympathetic regulation. We hypothesized that HRV would be lower in ASD and SCH groups compared to neurotypical controls (NTP), with the differences between groups diminishing during tasks. The experimental setup avoided additional stressors outside of the social context of the study.
Results: As hypothesized, we found significant differences in RMSSD between groups during the initial resting state (eyes open $F(2,111)=6.314$, $p=0.003$, $\eta p2=0.102$, eyes closed (EC): $F(2,98)=6.800$, $p=0.002$, $\eta p2=0.122$). Although HRV was nominally lower in the ASD group (EC: M_{ASD}= 26.10), only the SCH group (EC: M_{SCH}= 19.77) showed a significant difference from the NTP group (EC: M_{NTP}= 32.78) based on post hoc comparisons. Contrary to expectations, HRV did not significantly change in the SCH and NTP groups during tasks. However, in the ASD group, HRV increased after body scan relaxation and, notably, during cognitive tasks (group main effect in repeated measures ANOVA: $F(2,105)=6.068$, $p=0.003$). This suggests that the structured nature of the task may have a calming effect, observable in autonomic regulation.
Conclusions: Our findings indicate distinct autonomic regulation patterns in ASD and SCH, with structured situations potentially having a calming effect, particularly in individuals with ASD. In the next phase of our research, we will systematically examine the relationship between electrophysiological parameters and key symptoms such as attachment insecurity, mentalization deficits, disorganization, and the severity of clinical symptoms, all of which have significant implications for clinical conditions and everyday functioning.

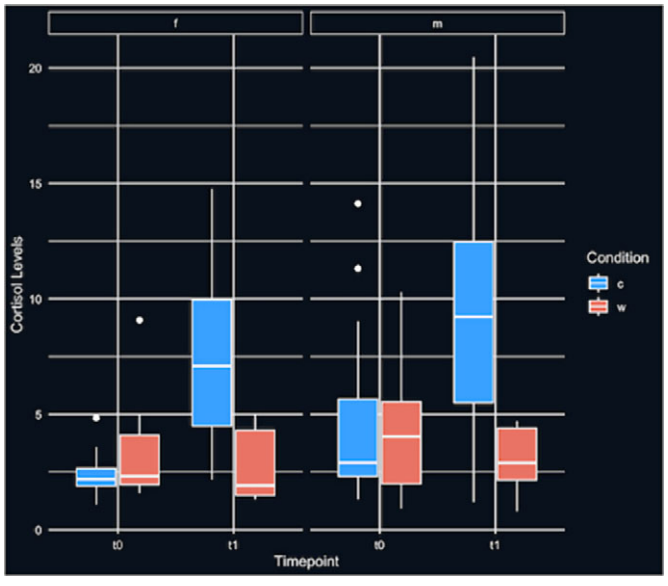
Objective Measures of Stress: Association of Speech Features and Cortisol

F. Menne[1]*, H. Lindsay[1], J. Tröger[1], A. König[1,2], M. Plichta[3] and M. Schmidt-Kassow[3]

[1]ki:elements GmbH, Saarbrücken, Germany; [2]Université Côte d'Azur, Centre Hospitalier et Universitaire, Clinique Gériatrique du Cerveau et du Mouvement, Centre Mémoire de Ressources et de Recherche, Nice, France and [3]Department of Psychiatry, Psychosomatic Medicine and Psychotherapy, University Hospital Frankfurt, Goethe-University Frankfurt am Main, Frankfurt, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.616

Introduction: Stress is a physiological and psychological response that contributes to the development and worsening of psychiatric



disorders such as depression and anxiety. Objective stress measurement is crucial in psychiatric settings, as stress affects the onset and progression of these conditions. Reliable data can improve diagnosis, treatment, and management. Speech analysis offers a non-invasive way to assess stress, as stress-induced physiological changes can influence features like pitch, jitter, and speaking rate.

Objectives: This study aims to explore whether automatic speech analysis can serve as an objective stress measure by examining the relationship between speech features and cortisol levels during an acute stressor.

Methods: Participants were recruited at the Department of Psychiatry, University of Frankfurt, Germany. Cortisol levels were measured in saliva before (T0) and 20 minutes after (T1) a stress-inducing or control task. Participants immersed their hand in cold or warm water while being observed via video, then completed a speech task by reading 16 standardized sentences before and after the task. Various speech features, including frequency, energy, and spectral characteristics, were analyzed in relation to cortisol levels. Correlations and mixed-effects models were calculated.

Results: A total of 52 participants (n=28 stress, n=24 control) read 1040 sentences across T0 and T1. Cortisol levels increased in both sexes in the stress condition compared to the control (Figure 1). Vocal tremor showed a strong positive correlation with cortisol at T0 and a strong negative at T1 regardless of condition. The harmonic-to-noise ratio had no correlation at T0 but displayed a negative one at T1. Pitch range showed no initial correlation but was strongly negative post-stress. Mixed-effects models revealed significant interactions between time point and group for features like number of pauses and loudness standard deviation ($p=.036$ and $p<.001$, respectively). Loudness rate was significantly associated with time point ($p<.001$). In the linear mixed-effects model, an interaction effect was observed between time point and group for the harmonics-to-noise ratio, with a significant decrease in the stress condition ($p<.001$).

Image 1:

Conclusions: This study supports speech analysis as a potential objective stress measure. Findings suggest that features like vocal tremor and pitch range are sensitive to acute stress, indicating that speech analysis could provide a non-invasive, real-time tool for assessing stress in psychiatric settings, offering an alternative to traditional self-report methods.

Adrenal gland volume measurement in depressed patients

L. Stepansky[1,2*], R. Ruppel[3], L. Sommerfeld[1,2], J. Kleiß[1,2], K. Türkan[1,2], S. Arndt[1,4], S. Bickelhaupt[1], F. Knoll[5], M. Uder[1,2,6] and M. May[1,2,6]

[1]Institute of Radiology, University Hospital Erlangen; [2]Friedrich-Alexander-University Erlangen-Nürnberg, Erlangen; [3]Department of Radiology, Charité - Universitätsmedizin Berlin, Berlin; [4]Medical Centre for Information and Communication Technology, University Hospital Erlangen; [5]Department Artificial Intelligence in Biomedical Engineering, Friedrich-Alexander-University Erlangen-Nürnberg and [6]Imaging Science Institute, University Hospital Erlangen, Erlangen, Germany

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.617

Introduction: Prior studies have shown contradicting results regarding adrenal gland volume (AGV) in depressed patients, with some reporting significant enlargement and others not.

Objectives: The aim of this study was to retrospectively compare CT image segmentations of the adrenal glands in patients with depression to a control group with stringent exclusion criteria to minimize confounding factors.

Methods: We included patients diagnosed with depression (ICD-10: F32/33) who underwent abdominal CT imaging between 2012 and 2022 and did not have any other psychiatric disorders. Diagnoses that could potentially influence AGV were excluded. The resulting 31 depressed patients were compared to a matching control group of 31 patients without depression. The AGV was manually segmented in thin-sliced reconstructions (≤1 mm).

Results: Total AGV in the depressed group was 6.78 (5.19-7.56) cm^3 compared to 6.90 (5.54-10.05) cm^3 in the control group. There was no significant difference in AGV between the two groups after adjusting for age, height, and weight. A positive correlation was observed between AGV and height ($r=0.41$, $p<0.001$) and weight ($r=0.52$, $p<0.001$). Males showed significantly larger AGV than females ($p\leq0.001$), and left AGV was significantly larger than right AGV ($p<0.001$). Patients within the depressed group who underwent imaging after a suicide attempt showed larger total AGV compared to the control group, though not statistically significant.

Conclusions: AGV is not increased in the well-selected cohort of depressed patients in this study, which contrasts with some previous reports in literature. Further multi-centric studies are required to identify potentially influencing factors such as attempted suicide.

Investigation of cytokine imbalance in schizophrenia, assessment of the possible role of serum cytokine levels in predicting treatment response, prognosis and psychotic relapses

K. Bodnar[1]*, L. Hermán[1], R. Zsigmond[1], J. Réthelyi[1], Á. Dénes[2] and K. Tóth[2]

[1]Department of Psychhiatry and Psychotherapy, Semmelweis University and [2]Laboratory of Neuroimmunology, HUN-REN Institute of Experimental Medicine, Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.618

Introduction: Schizophrenia, a multisystem chronic psychiatric disorder of unknown etiology, is associated with several immune dysfunctions, including abnormal levels of circulating cytokines. Emerging data suggest a potential causative role for cytokines in schizophrenia symptom development. Furthermore, disease duration, symptom severity, aggressive behavior, and cognitive deficits are correlated with levels of inflammatory cytokines. Despite the development of new antipsychotics, the negative and cognitive symptoms of schizophrenia often do not respond adequately to pharmacotherapy.
Objectives: 1. Can there be a cytokine or cytokines among the different cytokine levels detected in schizophrenia that can be used as biomarkers of treatment response? 2. Can changes in cytokine levels indicate the occurrence of psychotic relapse? 3. Can changes in the cytokine level play a role in predicting the prognosis of the disease?
Methods: We investigated cytokine levels in blood samples collected at hospital admission. Plasma levels of established inflammatory cytokines and chemokines have been measured by Cytometric Bead Array. The possible role of abnormal cytokine levels and their association with symptoms severity and their potential clinical implications have been investigated. The severity of the symptoms is monitored with the PANSS
Results: 16 schizophrenic patients who were hospitalized due to a psychotic relapse have been included. Blood samples were collected to measure cytokine levels, and the PANSS scale was recorded during a psychotic relapse. Additionally, we have included 11 age- and gender-matched healthy controls, from whom blood samples were also collected for cytokine measurement.. We found no differences plasma levels of G-CSF, GM-CSF, TNF, INF, VEGF, Il-6 and Il-10 in the patients compared with healthy controls. The levels of MCP-1 were higher in the schizophrenia patients than in the healthy control group.
Conclusions: These data demonstrated elevated plasma levels of MCP-1 in schizophrenia patients. The role of MCP-1 in various CNS disorders that involve inflammation is emerging. Among these, chronic inflammation reportedly contributes to the onset and progression of neurodegenerative disorders such as Parkinson's disease (PD), Alzheimer's disease (AD), and Multiple Sclerosis. Links between circulating MCP-1 levels and the progression of schizophrenia has also been suggested by previous studies and further studies are required understand the underlying mechanisms.
Significant outcomes: Patient with a psychotic relapse showed higher levels of plasma MCP-1 compared with healthy controls.
Limitation: The number of samples is too low to detect a statistically significant differences in blood MCP-1 during a psychotic relapse. Involvement of additional patients is ongoing.

Clozapine: overview of high-risk drug associations in French psychiatric hospitals. A multicenter survey on a given day

M. Bordes[1]*, R. Klein[1] and E. Queuille[2,3]

[1]Ferrepsy, Toulouse; [2]CH Charles Perrens, Bordeaux and [3]Association du réseau PIC, Armentieres, France
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.619

Introduction: Clozapine is the reference treatment for resistant schizophrenia. Its pharmacokinetic characteristics (metabolism by cytochromes CYP1A2, CYP2C19, and CYP3A4, among others) as well as its pharmacodynamic properties are the source of numerous high-risk drug interactions. According to the French marketing authorization, clozapine is contraindicated with bone marrow depressants, and associations with benzodiazepines, omeprazole, fluvoxamine, and lithium require specific precautions.
Objectives: Collaboration between a national multi-professional network operating in various public or private mental health hospitals (the PIC network) and a regional psychiatric research federation (FERREPSY Occitanie) enabled the implementation of a study describing the prevalence of high-risk drug associations in a large panel of French psychiatric hospitals
Methods: An observational cross-sectional study was conducted in December 2023 across 30 centers that are members of the PIC network and/or FERREPSY.
Results: The medical records of 795 patients were analyzed by hospital pharmacists from the participating centers. Several high-risk associations with clozapine were identified. In 1.5% of cases, clozapine was associated with carbamazepine, in 1.1% of cases with omeprazole, and in 3% of cases with fluvoxamine. More frequently, associations with lithium salts were found in 15.6% of patients and with benzodiazepines in 68.3% of patients.
Conclusions: This study provided an overview of high-risk co-prescriptions with clozapine in French psychiatric institutions. It highlights a high prevalence of certain high-risk associations, which underscore the discrepancy between clinical practices and health agency recommendations.

Effects of circulating tryptophan, kynurenine, kynurenic acid, IL-8, IFN-γ and IL-1β on neurocognition in clinically stable schizophrenia patients

M. Marković[1]*, T. Nikolić[2,3], M. Stašević[4], M. Stojković[5], M. Velimirović Bogosavljević[2,6], T. Stojković[2,3], S. Ristić[2], I. Stašević Karličić[4,7,8], S. Totić Poznanović[3] and N. Petronijević[2,3]

[1]Clinic for Psychiatry, University Clinical Centre of Serbia; [2]Institute for medical and clinical biochemistry; [3]Faculty of Medicine, University of Belgrade; [4]Clinic for Mental Disorders "Dr Laza Lazarević", Belgrade; [5]Clinic for neurology, University Clinical Centre of Niš, Niš; [6]University of Belgrade, Belgrade; [7]Faculty of Medicine, University of Priština – Kosovska Mitrovica, Kosovska Mitrovica and [8]Ministry of Health, Belgrade, Serbia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.620

Introduction: Cognitive impairments represent core features in schizophrenia, impact the functional capacity of patients, and are highly predictive of poor functional outcomes. There is a huge unmet need for improvement of these impairments, and the development of new therapies is conditioned by understanding underlying pathophysiology that is not clear enough. Kynurenic acid (KYNA) is the major matabolite of kynurenine (KYN) pathway (KP) of tryptophan (TRP) degradation, which acts as the inhibitor of NMDA and α7-nicotinic receptors that are crucial for cognitive functioning. Excessive antagonism of these receptors by KYNA is hypothesized to contribute to cognitive deficits while data indicate that proinflammatory cytokyines activate this TRP catabolic cascade.
Objectives: The objective of this study was to assess correlation between blood levels of TRP, KYNA, KYN, KYN/TRP ratio, IL-8, IFN-γ, IL-1β and cognitive functioning in clinically stable schizophrenia patients.
Methods: We measured plasma concentrations of TRP, KYNA, KYN, IL-8, IFN-γ, IL-1β and conducted assessment of cognitive functioning in domains of verbal memory, working memory, attention and processing speed, motor speed, verbal fluency, and executive functions using Brief Assessment of Cognition in Schizophrenia Scale (BACS) in 64 clinically stable schizophrenia (SCZ) patients. Patients were matched by age, sex and body mass index and exclusion criteria included obesity class 2 or higher, any concomitant organic mental or neurological disorder, acute or chronic inflammatory disease, and use of immunomodulatory drugs or psychoactive substances.
Results: A significant positive correlation was observed between BACS verbal fluency subtest score and kynurenine levels ($p<0.05$), along with a significant negative correlation with IL-β levels ($p<0.05$). There were no other significant correlations of blood levels of TRP, KYNA, KYN, KYN/TRP ratio, IL-8, and IFN-γ, and cognitive impairments in domains of verbal memory, working memory, attention and processing speed, motor speed, and executive functions.
Conclusions: While the relationship between KP metabolites and cognitive functioning in schizophrenia in domains of verbal and working memory is more reported, specific correlation between KYN levels and verbal fluency observed in our study is less studied and understood. Furthermore, negative correlation between IL-1β levels and verbal memory performance is a valuable finding and can be further explored in the context of suggested detrimental role of IL-1β on hippocampal neurogenesis. Our findings should be interpreted cautiously and corroborated in larger studies with parallel measurement of preferal and central levels of analyzed parameters since there are data that suggest that peripheral concentrations of TRP, KYNA, KYN, IL-8, IFN-γ, IL-1β do not mirror those in the central nervous system.

Evaluating the in-hospital initiation of 6-monthly paliperidone palmitate: a retrospective study

J. Mesones[1]*, A. Miller[1], A. Martínez[1] and G. Carretero[1]
[1]Psychiatry, Torrevieja University Hospital, Torrevieja, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.621

Introduction: Long-acting injectable antipsychotic treatments (LAIA) have marked a significant therapeutic advancement. For certain patients, clinical necessity may dictate that the most suitable treatment option is to initiate a 6-monthly LAIA earlier than standard protocols recommend. This can involve transitioning directly from an oral antipsychotic regimen or accelerating the switch from a monthly LAIA, a process known as alternative initiation.
Objectives: The objective of this study is to describe our experience with alternative initiation protocols for 6-monthly paliperidone palmitate (PP3M) in psychotic patients, as implemented at Torrevieja University Hospital.
Methods: This retrospective descriptive study utilized a sample selected through non-probabilistic consecutive sampling over a 27-month period (n=43). The study included patients who initiated 6-monthly paliperidone palmitate treatment through an alternative approach between May 2022 and August 2024 at Torrevieja University Hospital. All alternative initiations were performed in acute patients, who were decompensated at the time of initiating PP6M treatment, with very low therapeutic adherence. A descriptive analysis was conducted, with mean and standard deviation calculated for quantitative variables, and frequencies (N) and percentages calculated for categorical variables.
Results: Over the 27-month duration of this study, PP6M was administered to 43 patients (n=43). The average age was 41 years (SD ± 14.07). 53.49% (n=23) were male and 46.51% (n=20) female. The mean duration of disease progression was 6.67 years (SD ± 7.16). 20.9 % (n=9) of the patients were using substances with abuse potential. The diagnoses were distributed as follows: schizophrenia (32.56%), unspecified psychosis (30.23%), bipolar disorder (11.63%), delusional disorder (11.63%), borderline personality disorder (9.30%), and schizoaffective disorder (4.65%).
A total of 24 alternative initiations were made from oral antipsychotics, 15 from monthly paliperidone palmitate (PP1M), and 4 from aripiprazole LAIA 400 mg/month. During the 27-month study period, there were 4 hospital admissions and 7 visits to the emergency department. Treatment adherence after the alternative initiation of PP3M was 72 %, with patients completing all administrations on the scheduled dates. 74% of the patients are in outpatient follow-up. One patient experienced extrapyramidal symptoms as a side effect..
Conclusions: The present study indicates that there is a subset of patients who may benefit from an alternative initiation with PP6M, potentially enhancing adherence due to the simplified administration regimen. Initiating PP6M as an alternative, whether transitioning from oral antipsychotics, from PP1M or from another LAIA, could be an effective approach for managing decompensated patients with very low therapeutic adherence, demonstrating excellent tolerability and improved adherence.

The Quest to Find True ADHD: Navigating the Diagnostic Challenge of Malingering – A Systematic Review

G. Ratti[1]*, A. Callari[2], G. Nosari[2], A. R. Bianchi[1] and G. Delvecchio[2]

[1]Department of Pathophysiology and Transplantation, University of Milan and [2]Department of Neurosciences and Mental Health, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.622

Introduction: Attention-Deficit/Hyperactivity Disorder (ADHD) is a prevalent neurodevelopmental disorder and accurate diagnosis is essential but remains challenging due to the potential for malingering. Additionally, the increasing demands of a fast-paced society place, prompting quick solutions, may lead to simulated presentations or feigning. This paper examines the complexities of distinguishing genuine ADHD cases from malingering, emphasizing the need for refined diagnostic protocols. Malingering, in fact, involves deliberately fabricating symptoms to achieve a desired result, such as:

- **Academic Advantages**
- **Access to Medications**
- **Avoiding Responsibilities**

Objectives: Given all these challenges, we explored how current scientific literature addresses this issue. Inspired by the work of many colleagues, we aimed to summarize their efforts in this systematic review to propose a possible solution for collaborative improvement.
Methods: We analyzed over 296 papers from major scientific databases focusing on "malingering and ADHD" to create a comprehensive overview of this increasingly widespread problem.
Results: The main results, after a thorough analysis of all parameters, emphasize the need for:
1. Advanced Assessment and Objective Measures: dynamic assessment techniques, combined with psychophysiological measures and parental input.
2. Enhanced Diagnostic Protocols and Tools Integration: ADHD rating scales and Symptom Validity Tests (SVTs) like TOMM (Test of Memory Malingering) and WMT (Word Memory Test) to minimize diagnostic errors, make the criteria more robust.
The following table summarizes the criteria analyzed in the 37 articles selected after a thorough review.

Study Reference	Participants	Age	ADHD Assessment Tools	Malingering Assessment Tools	Comorbidities	Main Findings
Selected studies (37)	Diverse populations such as college students and ADHD patients.	Mean ages ranging from early 20s to late 20s; gender distribution varies.	Various scales including CAARS, BAARS-IV, ImPACT.	Several scales, including NV-MSVT, PAI, b Test, WMCD.	Commonly reported: anxiety and depression.	Challenges in differentiation, high prevalence of comorbidities, issues with malingering detection.

Conclusions: Traditional ADHD assessments, based heavily on self-reported symptoms, are becoming less reliable, especially with the growing trend of self-diagnosis and malingering. To address this, adding performance-based tests like TOMM and WMT is key for spotting malingering and improving diagnosis accuracy. Our study aims to elucidate this issue, which has subtle but profound implications for the quality of life of thousands of patients, who may receive a superficial diagnosis that could affect them for a lifetime, even pharmacologically.

Gender difference in eye dominance in patients with schizophrenia and normal controls

K. V. Akabalieva

Medical University, Sofia, Bulgaria
doi: 10.1192/j.eurpsy.2025.623

Introduction: Hemispheric imbalance might underlie the genesis of psychosis. In patients with schizophrenia left eye dominance was higher than in control subjects. The aim of the study is to investigate sexual differences in left eye dominance as a biological marker of neuronal dysontogenesis in schizophrenic patients and control subjects. This study is part of a larger investigation project on the intriguing relations between six groups of markers of neuronal dysontogenesis - left-handedness, left-footedness, left-eyedness, minor physical anomalies, digit ratio, and cognitive (attention and memory) deficit.
Objectives: Altered cerebral lateralization is a key trait found in many neurological and psychiatric disorders. This study investigates the gender difference in eye dominance between patients with schizophrenia and controls.
Methods: The study was conducted in the Clinic of Psychiatry at the University Hospital in Sofia and the State Psychiatric Hospital in Radnevo. The sample included 98 (56 men, 42 women) consecutively admitted schizophrenic inpatients with a mean age 34.45 years for men and 42.20 years for women and 82 control subjects (30 men, 52 women) with a mean age 34.70 for men and 44.50 years for women. Three tests for eye dominance were administered as performance tasks- Looking through a monocle, Hole test and Porta test.
The non-parametric Mann-Whitney test was used to analyse the data.
Results: The mean left-eyedness is significantly higher in schizophrenic patients than in control subjects in the three eye tests: Looking through a hole - .81 vs. .39, p<.001, over two times increase; Looking through a monocle - .78 vs. .39, p<.002, two times increase; Porta test - .86 vs. .41, p<.002, over two times increase.
In male subjects the difference between schizophrenia and controls reaches statistical significance for Looking through monocle (p=.037), but does not reach statistical significance for Hole test (p=.196) and Porta test (p=.077). In contrast, all female intra-gender comparisons between schizophrenia and controls reach statistical significance- Looking through monocle (p=.013) and Porta test (p=.015) reach statistical significance at p<.05, while Hole test at p=.001.
Conclusions: The patients with schizophrenia have significantly higher mean left-eyedness than the controls in both sexes, but this difference is much more pronounced in women than in men for all three eye tests. Altered eye dominance in patients with schizophrenia is related to a prenatal maldevelopment and exhibits clear gender difference.

Neurological Soft Signs in Patients with Schizophrenia May be Related to Treatment Resistance

S. Elmas[1]* and A. Üçok[2]

[1]Psychiatry, Kahta State Hospital, Adıyaman and [2]Psychiatry, Istanbul University Istanbul Faculty of Medicine, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.624

Introduction: Motor abnormalities in schizophrenia are important as they are measurable objective parameters. Neurological soft signs (NSS), which are one of the primary motor abnormalities, are minor motor and sensory abnormalities that cannot be localised to a specific brain region, reflect the areas of sensory integration, motor coordination and motor sequencing. Instrumental measures of motor abnormalities have the potential to improve detection, early intervention and treatment strategies in psychotic disorders.
Objectives: Our aim in this cross-sectional study was to compare NSS in patients with treatment-resistant schizophrenia (TRS) and treatment responsive schizophrenia (non-TRS) and healthy controls (HC), and to examine the relationship of NSS with sociodemographic and clinical variables, premorbid adjustment, functioning, negative and cognitive symptoms.
Methods: 30 TRS patients, 30 non-TRS patients and 30 HC were included in the study between November 2021 and November 2022. The inclusion criteria for the TRS group were to meet the criteria for resistance to antipsychotic treatment. Neurological Evaluation Scale (NES) was applied to all participants to evaluate NSS. The scale assesses impairment in four different functional areas: "sensory integration", "motor coordination", motor sequencing" and "other signs". Brief Psychiatric Rating Scale (BPRS), Brief Negative Symptom Scale, General Assessment of Functioning (GAF), Clinical Global Impression-Severity Scale (CGI-S), Premorbid Adjustment Scale-Childhood (PAS), and a cognitive battery were applied to patients with schizophrenia. The authors declare that all methods used in this study adhere to the ethical guidelines of the corresponding national and institutional review boards for human research and are in alignment with the 1975 Helsinki Declaration, as updated in 2008. All participants provided written informed consent to participate in this study.
Results: We found significant differences in the NES-Total score and all subscale scores between patients with schizophrenia and HC (all comparisons p<0,001). NSS in patients with schizophrenia were found to be higher than in HC. TRS had higher NES-Total (p=0,002), NES-Sensory Integration (p=0,001), and NES-Other Signs (p<0,001) scores than non-TRS. NES-Total score was negatively correlated with GAF score and positively correlated with BPRS, CGI-S and PAS-childhood scores. Poor performance on cognitive tests was associated with more NSS. Only the sensory integration deficits were found to be associated with negative symptoms.
Conclusions: Our findings suggest that NSS examination in patients with schizophrenia may indicate treatment resistance or response. NSS are associated with severity of illness, lower functioning, poor premorbid adjustment, and poor cognitive performance. Longitudinal studies involving larger samples are needed to understand the course of NSS at different stages of the illness.

Cariprazine in multiple-episode dual schizophrenia: post-hoc analysis of an observational study

N. Szerman[1]*, Z. B. Dombi[2], P. Vega[3], C. Roncero[4], L. Peris[5], L. Grau-López[6] and I. Basurte-Villamor[3]

[1]Gregorio Marañón University Hospital, Madrid , Spain; [2]Gedeon Richter Plc. , Budapest, Hungary; [3]Francisco de Vitoria University, Madrid; [4]University of Salamanca Healthcare Complex, Salamaca, Spain; [5]Centre Neuchâtelois De Psychiatrie, Marin-Epagnier, Switzerland and [6]University Hospital Vall d'Hebron, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.625

Introduction: Schizophrenia frequently coexists with substance use disorders, especially cannabis use disorder (CUD). Importantly, cannabis use is known to further exacerbate symptoms, leading to more frequent and severe psychotic episodes, longer hospital stays and poorer overall treatment outcomes. The lifetime risk of relapse is around 60%. Therefore, the treatment of patients with multiple episodes is even more challenging
Objectives: To evaluate the effectiveness of cariprazine in schizophrenia patients with multiple episodes and comorbid cannabis use disorder.
Methods: This was a 6-month, multi-centre, observational study conducted at six institutions in Spain. The study included adult outpatients aged 18 to 65 years, diagnosed with schizophrenia and cannabis use disorder according to the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) criteria, who were receiving cariprazine treatment based on medical judgment. Exclusion criteria included pregnant or breastfeeding women and patients with co-existing medical conditions that could potentially skew the study results.
The study evaluated changes in schizophrenia symptoms using the Positive and Negative Syndrome Scale (PANSS) and the Clinical Global Impression-Schizophrenia (CGI-SCH), as well as changes in CUD symptoms based on the Cannabis Abuse Screening Test (CAST) and the Severity of Dependence Scale (SDS). This post-hoc analysis focused on patients with multiple episodes. Patient characteristics were summarized using descriptive statistics. Least squares (LS) means were calculated for the change from treatment start to treatment end for PANSS, CGI-SCH, CAST, SDS using a mixed model for repeated measures. All analyses were conducted using SAS.
Results: From the cohort, 38 (65%) patients had multiple episodes. The mean age of these patients was 36.5 and 65.8% of them was male. Most patients received 4.5 mg/day cariprazine at baseline (60.5%). Half of the patients also took concomitant antidepressants and/or antipsychotics. Throughout the 6-month observational period significant improvement was detected in both schizophrenia (LS mean change in PANSS Total score: -46.2, p<0.001, CGI-SCH Total score: -8.0, p<0.001) and CUD symptomatology (LS mean change in CAST Total score: -6.6, p<0.001, SDS Total score: -8.0, p<0.001).
Conclusions: Cariprazine seem to be an effective treatment option for schizophrenia patients with multiple episodes and comorbid CUD.

The Impact of Autistic Traits on Social Cognitive Performance in Schizophrenia Spectrum Disorders

Y. E. Turan[1]*, B. Verim[1], Y. Dokuyan[2], A. Küçükakdağ[1], E. Cesim[1], B. Yalınçetin[1] and E. Bora[1,3,4]

[1]Department of Neurosciences, Dokuz Eylul University; [2]Departmant of Psychiatry, İzmir City Hospital; [3]Departmant of Psychiatry, Faculty of Medicine, Dokuz Eylul University, İzmir, Türkiye and [4]Departmant of Psychiatry, University of Melbourne and Melbourne Health, Melbourne Neuropsychiatry Centre, Carlton South, Victoria , Australia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.626

Introduction: Social cognition impairments are well-recognized in both Schizophrenia Spectrum Disorders (SSDs) and Autism Spectrum Disorder (ASD), significantly impacting interpersonal relationships and overall quality of life. While some studies have suggested differences in social cognition between these two disorders, recent research has shown that these differences may be non-significant when controlling for factors such as age and symptom severity(Pinkham et al. Psychol Med 2019; 1-9). Given the overlap in symptoms and the potential for autistic traits to influence social cognitive functioning in SSD, it's crucial to investigate how these traits can impact social cognition in individuals with SSD.
Objectives: The aim of this study is to evaluate autistic traits in SSD and its relation with social cognition and clinical variables.
Methods: 73 participants with SSD (56 patients (mean age 37.80 ± 11.519) with schizophrenia and 17 patients (mean age 36.47± 10.909) with schizoaffective disorder) participated in the study. All participants were interviewed using the Structured Clinical Interview for DSM-IV. Current psychotic, negative and positive symptoms of all patients were evaluated using the Scale for the Assessment of Positive Symptoms and the Brief Negative Symptom Scale (BNSS). The Screen for Cognitive Impairment in Psychiatry(SCIP) was used for measuring cognitive function. Autistic traits are evaluated with the Comprehensive Autism Trait Inventory (CATI). In the assessment of social cognition, facial emotion recognition was evaluated with Penn Emotion Recognition Test (PERT), theory of mind was assessed Reading Mind in The Eyes (RMET) task.
Results: Total CATI scores weren't correlated with RMET and PERT scores. Communication and social camouflage subscores of CATI were negatively correlated with total RMET score (r=-0.289, p=0.013; r=-0.265, p=0.024). CATI total/subscale scores didn't have a relationship with age, education years, BNSS and SCIP scores. SCIP score was correlated with RMET(r=0.358, p<0.01) and PERT (r=0.259, p=0.027). Age had a negative relationship with RMET(r=-0.27, p=021) and PERT (r=-0.397, p<0.01) scores while education was positively correlated with RMET even though the the strength was low (r=0.246, p=0.036).
Conclusions: Contrary to expectations, the results did not show a relationship between higher autistic traits in SSD and social cognitive performance. The social subscales of CATI revealed a negative correlation between higher autistic traits and theory of mind performance, but no correlation with emotion recognition. In accordance with literature, aging shows a relationship with lower social cognition scores. Future research should further investigate how autistic traits impact theory of mind deficits in SSD. Interventions regarding social cognitive deficits with age should be evaluated.

Diagnostic Stability and Predictive Factors of Acute and Transient Psychotic Disorders: A Retrospective Study from Turkey

I. Yelli[1]*, B. Koparal[1], S. Özcelep[1] and M. H. Aksu[1]

[1]Department of Psychiatry, Gazi University Faculty of Medicine, Ankara, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.627

Introduction: The 10th edition of the International Classification of Diseases (ICD-10) categorizes acute and transient psychotic disorders (ATPD) as a composite group that merges traditional acute psychosis definitions, characterized by acute onset (≤15 days) and rapid resolution (1-3 months), often linked to stress (WHO, 1992). The incidence of ATPD ranges from 4-10 per 100,000, with a prevalence between 5.8% and 19% (Marneros *et al.* Cambridge University Press 2004; Queirazza *et al.* BJPsych 2014; 204:299-305), predominantly affecting middle-aged to older individuals and females. Diagnostic stability for ATPD varies, with reported values between 35.9% and 56% (Aadamsoo *et al.* Nord. J. Psychiatry 2011; 65:381-8; Poon *et al.* Nord. J. Psychiatry; 2017; 71:139-44), influenced by factors such as age of onset, gender, comorbid substance use and symptom overlap (Taş *et al.* Noro Psikiyatr Ars 2019; 56:47-51). Studies indicate that the highest diagnostic consistency is linked to schizophrenia diagnoses (Queirazza *et al.* BJPsych 2014; 204:299-305).
Objectives: This study retrospectively investigates the temporal stability of first-episode ATPD over a three-year follow-up period. Furthermore, it aims to explore whether initial clinical presentations and sociodemographic factors may serve as prognostic indicators for diagnostic transitions to schizophrenia or other psychotic disorders.
Methods: Patients diagnosed with ATPD and followed over 3 years were evaluated retrospectively. Socio-demographic and clinical variables potentially associated with diagnostic transitions were investigated. The study was approved by the Gazi University School of Medicine Ethics Committee (2023-889).
Results: 106 patients (57 males, 49 females) with a mean age of 29.90 ± 10.33 years were included. The diagnostic stability of ATPD was found to be 17.8%. Additionally, 62.3% of the subjects received a diagnosis of schizophrenia or other psychotic disorders. Significant differences were observed between diagnostic groups with regard to education level ($\chi^2 = 9.776$, $p = 0.008$) and hospitalization rates ($\chi^2 = 8.083$, $p = 0.018$). Multivariate logistic regression analysis indicated that younger age at onset (OR = 0.951, 95% CI 0.90−0.96; p = 0.032) and lower educational attainment (OR = 0.219, 95% CI 0.08−0.54; p = 0.001) were significantly associated with a diagnostic shift to schizophrenia or other psychotic disorders.
Conclusions: In Turkey, the diagnostic stability of ATPD is notably low, with the most common diagnostic shift being towards schizophrenia-related disorders. To our knowledge, no comprehensive studies have been conducted in Turkey that evaluate patients diagnosed with ATPD. Therefore, our study aims to contribute to the existing literature. Further research involving larger sample sizes is needed to assess the influence of clinician attitudes and stigma on diagnostic changes.

Exploring the Links between Complex Post-Traumatic Stress Disorder and Psychotic-Like Experiences in Adolescents: A Gaussian and Bayesian Network Approach

T. B. Jannini[1]*, G. Terrone[2], L. Sideli[3], C. Niolu[2], G. Di Lorenzo[2], A. Schimmenti[4] and R. Rossi[2]

[1]Department of Experimental Medicine; [2]Department of Systems Medicine, Tor Vergata University of Rome; [3]Department of Human Sciences, LUMSA University of Rome, Rome and [4]Scienze dell'Uomo e della Società, Università degli Studi di Enna "Kore", Enna, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.628

Introduction: Complex post-traumatic stress disorder (cPTSD) is a recently recognized condition characterized by the combination of core PTSD symptoms—re-experiencing, avoidance, and hyperarousal—alongside disturbances in self-organization (DSO), which include affective dysregulation, negative self-concept, and interpersonal difficulties. Emerging evidence suggests that these complex symptom domains not only lead to greater functional impairment compared to PTSD but are also closely associated with the onset of psychotic-like experiences (PLEs). PLEs, which encompass subthreshold cognitive and perceptual anomalies such as hallucinations and delusional thinking, are increasingly viewed as critical indicators of vulnerability to more severe psychopathological outcomes. Given the developmental vulnerability during adolescence, the intersection of cPTSD and PLEs during this period is of significant concern, particularly as it may signal the emergence of broader psychopathological trajectories.
Objectives: The primary aim is to identify the key cPTSD symptoms driving the comorbidity with PLEs in adolescents using two different network analysis approaches. We indeed seek to clarify what symptoms explain are modt central in the relatioship between PTSD/cPTSD and PLEs and elucidate the directionality of these symptom relationships. We finally aim to also explore whether gender moderates these associations within the network structures. We hypothesize that cPTSD symptoms are central in understanding the relationship between trauma and PLEs.
Methods: A group of 1,010 late adolescents was assessed for post-traumatic symptoms and PLEs. The study involved estimating the Gaussian Graphical network structure for PTSD/cPTSD symptoms and PLEs, examining their bridge centrality indices. Subsequently, a Bayesian network analysis was conducted to create a directed acyclic graph (DAG). Gender was considered a moderator in both the Gaussian and Bayesian models.
Results: Findings revealed that affect dysregulation, a domain of cPTSD, had the strongest connection with the PLEs cluster. The Bayesian network analysis showed a pathway linking cPTSD symptoms of worthlessness and interpersonal difficulties to PLEs symptoms like paranoia and social anxiety. Additionally, gender differences were observed in both network models.

Image 1:

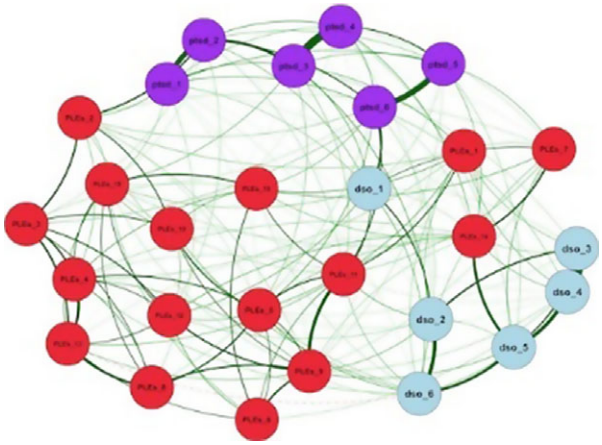

Image 2:

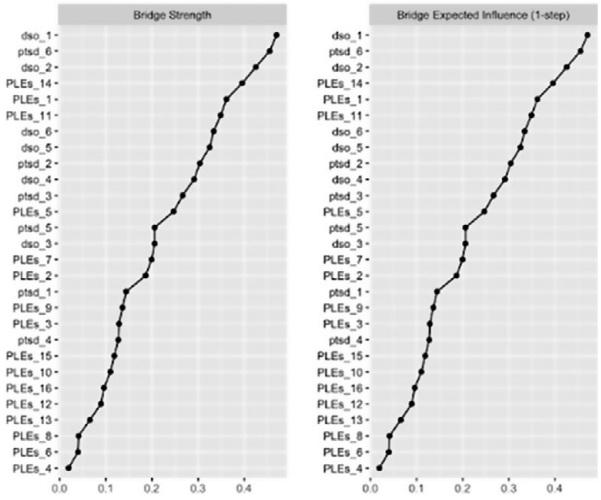

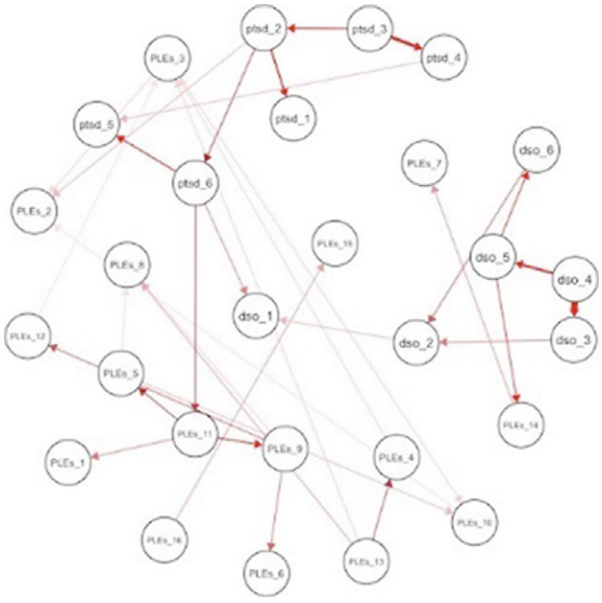

Image 3:

Conclusions: The study emphasizes the pivotal role of affect dysregulation and a negative self-concept in associating cPTSD with PLEs, highlighting gender-specific differences. These results point to the importance of gender-sensitive strategies in preventing and treating PLEs in adolescents, stressing the need for early intervention and customized treatment plans.

Coping, Perceived Stress, And Life Satisfaction Among Female Doctors in a Low Middle-Income Country

S. Q. Bokhari[1]*, A. Butt[1], A. Manzoor[2], A. Waheed[1] and S. Ijaz[2]

[1]Psychiatry, Services Institute of Medical Sciences and [2]Psychology, Services hospital Lahore, Lahore, Pakistan
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.629

Introduction: This research explores the intricate relationship between coping strategies, perceived stress levels, and life satisfaction among female medical professionals. The medical field is known for its rigorous demands, and understanding how lady doctors manage stress and its impact on their overall life satisfaction is crucial. While previous studies have shed light on stress-related issues in medical undergraduates, there is a significant gap in research focused on the well-being of practicing female doctors.
Objectives: The objectives of this study are to investigate the relationship between coping behaviors and stress levels among lady doctors, assess the role of coping behaviors in shaping life satisfaction, explore the connections between coping behaviors, life satisfaction, and stress, and analyze the influence of demographic factors such as age and marital status on coping life satisfaction, and stress perception.
Methods: This study utilizes a quantitative research design and a purposive sample of lady doctors from government hospitals in Pakistan. Key measures include the COPE Inventory to assess coping behaviors, the Satisfaction with Life Scale to gauge life satisfaction, and the Perceived Stress Scale to measure stress levels. These tools allow for a comprehensive examination of the intricate interplay between these variables. SPSS 21 was used to analyze the data.
Results: Results indicated that Coping is negatively correlated with Stress ($r = -.29$, $n = 100$, $p = 0.05$) meaning that higher coping strategies are associated with lower stress levels. Similarly, Coping is positively correlated with Life Satisfaction ($r = .36$, $n = 100$, $p = 0.05$) indicating that higher coping strategies are associated with higher life satisfaction. Likewise, Stress is negatively correlated with Life Satisfaction ($r = -.22$, $n = 100$, $p = 0.05$), suggesting that higher stress levels are associated with lower life satisfaction. Also, there is a statistically significant difference in coping between Single and Married individuals ($t = 2.2$, $df = 36.6$, $p = 0.03$), with Single individuals showing higher coping scores.
Conclusions: The findings of this study provide valuable insights into the psychological well-being of female medical professionals in Pakistan. This research contributes to the broader discourse on the well-being of healthcare professionals, shedding light on the unique experiences of female doctors in a challenging healthcare environment. Ultimately, it aims to inform policies and practices that support the psychological resilience and job satisfaction of female doctors, ensuring they can continue providing high-quality healthcare services to their communities.

Impact of early menarche on increased anxiety levels in female patients

K. Laskarin[1]*, E. Ivezic[1,2], E. Gudelj[1], S. Belcic[1], K. Matic[1], N. Ruljancic[1], V. Grosic[1,2], I. Filipcic[1,2,3] and S. Vuk Pisk[1,2]

[1]University Psychiatric Hospital Sveti Ivan, Zagreb; [2]Faculty of Dental medicine and Health Osijek, Osijek and [3]School of Medicine University of Zagreb, Zagreb, Croatia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.630

Introduction: Previous studies show contradictory results about the relationship between the age of menarche and the intensity of anxiety symptoms. Some studies found that anxiety symptoms were significantly higher in patients with earlier age of onset of menarche. Recent studies show that early puberty and menarche are associated with greater rates of morbidity of anxiety and other psychiatric illnesses than relatively late menarche. It is presumed that girls who achieve menarche earlier are less prepared for puberty and tend to have more negative emotions associated with menstruation.
Objectives: The purpose of this research was to determine the correlation between onset of menarche and intensity symptoms of anxiety in female patient with affective and anxiety disorders.
Methods: The research is prospective and includes female patients with established diagnoses of depressive disorder, anxiety-depressive disorder, bipolar disorder (depressive episode) aged 18-65. The patients had their laboratory parameters determined, including sex hormones (estrogen, progesterone, testosterone, FSH, LH and prolactin), filled out a demographic questionnaire and questionnaires: The Suicide Behaviors Questionnaire-Revised (SBQ-R), Generalised Anxiety Disorder Assessment (GAD-7), Patient Health Questionnaire (PHQ-9), Beck Depression Inventory (BDI-II), Beck Anxiety Inventory (BAI), Matthey Generic Mood Question , Montgomery-Asberg Depression Rating Scale (MADRS), Hamilton Anxiety Rating Scale (HAMA) i Hamilton Depression Rating Scale (HAMD).
Results: The preliminary data of the prospective study showed that there was a statistically significant proportion of patients in whom a correlation was found between the age of onset of menarche and the intensity of anxiety.
Conclusions: Age of menarche could be an influence on intensity of anxiety symptoms in female patients.

Affective temperaments as potential predictors of medication adherence and infertility treatment outcomes: results from a prospective longitudinal study

G. Szabó[1,2]*, J. Szigeti F[3], M. Sipos[4], S. Várbíró[4] and X. Gonda[5,6]

[1]Doctoral School, Semmelweis University; [2]Department Of Psychiatry, North Centre Buda New Saint John Hospital and Outpatient Clinic; [3]Institute of Behavioral Sciences; [4]Department of Obstetrics and

Gynecology; [5]Department of Psychiatry and Psychotherapy and [6]NAP3.0-SE Neuropsychopharmacology Research Group, Hungarian Brain Research Program, Semmelweis University, Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.631

Introduction: Recent research suggests that psychological and personality factors, specifically affective temperaments, may influence adherence to prescribed pharmacotherapeutic interventions. However, this relationship has not yet been investigated in the context of infertility treatments.
Objectives: Our prospective longitudinal study aimed to assess the impact of affective temperaments on medication adherence during infertility treatments.
Methods: Among women presenting for infertility treatment at the Semmelweis University Assisted Reproduction Centre, we administered the Temperament Evaluation of Memphis, Pisa, Paris, and San Diego (TEMPS-A) questionnaire before treatment to assess their affective temperament and the Morisky Medication Adherence Scale (MMAS) questionnaire six months after treatment initiation to measure their medication adherence during treatment. The effect of affective temperaments on medication adherence was analyzed using linear regression models. All statistical analyses were performed using R statistical software version v4.4.1.
Results: In this paper, we present preliminary partial results. In our cohort of 121 women undergoing infertility treatment, higher hyperthymic affective temperament score predicted significantly higher adherence to pharmacotherapy recommendations ($\beta = 0.11$, $p = 0.042$), while the other four dominant affective temperaments predicted significantly poorer medication adherence (cyclothymic: $\beta = -0.15$, $p<0.001$, depressive: $\beta = -0.21$, $p=0.001$, irritable: $\beta = -0.14$, $p=0.004$, anxious: $\beta = -0.09$, $p=0.011$).
Conclusions: The results suggest that affective temperaments may affect adherence to prescribed pharmacotherapeutic interventions among women undergoing infertility treatment, which may thereby influence the outcome of infertility treatment administered. By screening for affective temperament profiles, it would be possible to identify patient groups at high risk of drug non-adherence and then to aid adherence by applying patient-tailored treatment, including psychological interventions, which could increase the chances of successful pregnancy among women undergoing in vitro fertilization treatment.

Neuropsychiatric Manifestations in Thyroid and Sex Hormone Disorders: A Comprehensive Review

C. Kalogirou[1]*, C. Christou[2], V. Zacharopoulou[3], A. Potamianou[3], T. Soumala[4] and G. P. Chrousos[5]

[1]University of Patras, Patras, Greece; [2]Marien hospital, Dusseldorf, Germany; [3]Hospital of Leros, Leros; [4]University of Ioannina, Ioannina and [5]Medical School, University of Athens, Athens, Greece
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.632

Introduction: Thyroid and sex hormones play pivotal roles in the regulation of various physiological processes, including brain function. Dysregulation of these hormones has been increasingly associated with a range of neuropsychiatric disorders, including depression, anxiety, cognitive impairment, and mood disorders.
Objectives: This review aims to systematically examine the correlation between thyroid and sex hormones disorders and the spectrum of emerging neuropsychiatric manifestations, enlightening the pathophysiological mechanisms.
Methods: A literature search was performed in many databases including PubMed, Web of Science, and Google Scholar for studies published in recent years. Eligible randomized controlled trials, observational studies, and systematic reviews examining neuropsychiatric outcomes in patients with thyroid or sex hormone disorders were included. Findings were synthesized both quantitatively, with meta-analyses where possible, and qualitatively, with thematic analysis for heterogeneous data.
Results: The review identified a strong association between thyroid dysfunctions and neuropsychiatric disorders such as depression, anxiety, and cognitive decline. Hypothyroidism was consistently linked with depressive symptoms likely due to impaired serotonergic and dopaminergic neurotransmission, along with decreased hippocampal neurogenesis. Conversely, hyperthyroidism, characterized by elevated thyroid hormone levels, was associated with heightened anxiety, irritability, and emotional lability, possibly through dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis and increased sympathetic nervous system activity.
In the context of sex hormone disorders, estrogen deficiency during menopause was correlated with a significant increase in behavioral and cognitive impairments, potentially mediated by reduced modulation of serotonin receptors, diminished synaptic plasticity, and increased neuroinflammatory responses. Similarly, testosterone decline in aging men was linked to mood and cognitive disorders, with evidence pointing to disruptions in androgen receptor signaling and alterations in γ-aminobutyric acid (GABA)ergic and glutamatergic pathways.
Conclusions: This review underscores the significant link between thyroid dysfunctions, particularly hypothyroidism and hyperthyroidism and mood disorders such as depression and anxiety, while also indicates that estrogen deficiency and testosterone decline contribute to cognitive impairments and emotional disturbances. These findings help the healthcare providers to recognize neuropsychiatric symptoms as potential indicators of underlying endocrine disorders.

A look at Hypoactive Sexual Desire Disorder in Women

I. Santos[1]*, F. Cunha[1], R. Andrade[1], N. Castro[1], R. Cabral[1], C. Cunha[1], P. Pires[1] and B. Melo[1]

[1]Departamento de Psiquiatria e Saúde Mental, ULS Viseu Dão Lafões, Viseu, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.634

Introduction: Hypoactive sexual desire disorder (HSDD) is an underdiagnosed and poorly treated condition that is highly prevalent among women. Characterised by a persistent or recurrent deficiency of sexual desire, HSDD leads to significant personal distress and

interpersonal difficulties, and can adversely affect emotional well-being and intimate relationships.
Objectives: The aim of this review is to discuss the aetiology, diagnosis, and treatment of HSDD.
Methods: A comprehensive literature search was conducted using the electronic database PubMed. The keywords used for the search included "Hypoactive Sexual Desire Disorder", "treatment", and "aetiology and diagnosis".
Results: The search yielded a total of five systematic reviews. These studies concluded that the aetiology of HSDD involves a complex interaction of biological, psychological, and sociocultural factors. The diagnosis of this disorder should include a comprehensive sexual and medical history to rule out other causes. Treatment options for HSDD are multifaceted, incorporating both pharmacological and non-pharmacological approaches.
Conclusions: HSDD may be caused by biological factors such as a reduction in sexual excitation signals, an increase in sexual inhibition signals, or a combination of both. Testosterone plays a crucial role in initiating sexual activity, desire, and behaviour, through its influence on vaginal lubrication, sensation, and clitoral engorgement. Low oestrogen levels are associated with dyspareunia and changes in the vulvovaginal mucosa. Progesterone, serotonin, dopamine, and noradrenaline also play a role in the physiology of sexual desire. Psychological factors, particularly a lack of emotional intimacy, communication difficulties, negative body image perceptions and low self-esteem, can also reduce sexual desire. Depressive and anxiety disorders can significantly affect sexual desire. Sociocultural factors, such as religious beliefs and traditional values, can have a negative impact on sexuality. The diagnosis is made through a detailed clinical history, which may be supported by a screening tool, the Decreased Sexual Desire Screener (DSDS), as well as laboratory and imaging investigations. Identified modifiable factors, such as illicit substance abuse, sleep problems, medication use, and various medical and psychological factors, should be addressed first. For women without remaining modifiable factors who need psychological support, sex therapy, cognitive-behavioural therapy, and couples therapy are recommended. In premenopausal women, pharmacological treatment with flibanserin or bremelanotide may be considered. In postmenopausal women, hormonal therapy with testosterone may be considered off-label. The combination of psychological and pharmacological interventions is the most effective approach for HSDD. However, further studies are needed to better understand the pathological mechanisms of HSDD and to develop new therapeutic options.

Exploring the effects of theta burst stimulation on craving severity and biomarkers in patients with gambling disorder

H.-M. Chang[1,2]

[1]Institute of Epidemiology and Preventive Medicine, National Taiwan University and [2]Songde Branch, Taipei City Hospital , Taipei, Taiwan, Province of China
doi: 10.1192/j.eurpsy.2025.635

Introduction: Gambling disorder, previously known as pathological gambling, is a behavior that significantly impairs functioning in personal, social, and occupational domains. Currently, there is no pharmacological treatment for gambling disorder, emphasizing the need for innovative treatment modalities. Imaging studies have identified a connection between prefrontal circuit dysfunction and behavioral disinhibition, supporting the potential use of non-invasive brain stimulation in treating gambling disorder.
Objectives: The purpose of this study is to investigate the effect of theta-burst stimulation (TBS) on gambling disorder.
Methods: The study duration is 2 weeks, with 10 sessions of TBS intervention. The intervention group will receive 1800 pulses of intermittent TBS at the left dorsolateral prefrontal cortex and 1200 pulses of continuous TBS at the pre-supplementary motor area during each session, while the control group will receive sham stimulation. Primary outcomes, including the Gambling Symptom Assessment Scale (G-SAS) and the Visual Analogue Scale (VAS) for craving, were administered at weeks 0, 2, 4, and 8, and the changes between the two groups were compared using generalized estimating equations. Secondary outcomes, including Beck Anxiety Inventory and Beck Depression Inventory, and serum brain-derived neurotrophic factor (BDNF), cortisol, and hsCRP, were measured at weeks 0, 4, and the changes between the two groups were compared using repeated measures ANOVA.
Results: A total of 33 patients with gambling disorder were randomly assigned in a 2:1 ratio to the intervention group (21 patients) and the control group (12 patients) on a double-blind basis. They were included in the preliminary analysis on an intention-to-treat basis. The VAS scores of the active group decreased more than those of the sham group (active group: 53.3 to 17.9, sham group: 37.5 to 15.3), but the difference did not reach statistical significance ($p = 0.13$). Compared to the sham group, the active group showed a decreasing trend in hsCRP ($p = 0.54$) and an increasing trend in free BDNF ($p = 0.34$), but neither reached a statistically significant difference.
Conclusions: Drawing definitive conclusions is limited by small sample size. Nevertheless, the initial results from this study suggest that the alterations in levels of gambling craving, hsCRP, and serum BDNF align with our hypothesis.

Cluster analysis of relapse risk factors in alcohol use disorder

J. Gajdics[1]*, O. Bagi[1], F. F. Farkas[1], B. K. Kádár[1], I. K. Pribék[1], B. Andó[1] and B. A. Lázár[1]

[1]Department of Psychiatry, University of Szeged, Albert Szent-Györgyi Medical School, Szeged, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.636

Introduction: The chronic relapsing nature of alcohol use disorder (AUD) makes treatment and recovery especially difficult. One of the most prevalent factors contributing to relapse is craving, which is a strong urge to drink alcohol. Moreover, alcohol withdrawal symptoms experienced during abstinence can trigger the urge to

drink alcohol. Furthermore, stress and anxiety can also elicit craving and increase the motivation to drink alcohol.
Objectives: Further understanding the risk of relapse would be crucial for the treatment of AUD. Thus, the aim of this study was to identify clusters within a sample of patients with AUD based on the different factors of relapse risk, and to compare these clusters based on the severity of alcohol use disorder, craving and anxiety.
Methods: The sample consisted of 114 patients diagnosed with AUD at the Department of Psychiatry, University of Szeged, Hungary between November 2022 and January 2024. The level of AUD was measured with the Alcohol Use Disorders Identification Test (AUDIT) (subscales: consumption, dependence, harmful consequences of alcohol use) and the Severity of Alcohol Dependence Questionnaire (SAD-Q) (subscales: physical withdrawal signs, affective withdrawal signs, withdrawal relief drinking, quantity and frequency of alcohol consumption, rapidity of reinstatement of withdrawal symptoms following abstinence). State and trait anxiety were measured with the State-Trait Anxiety Inventory (STAI-S, STAI-T). Craving was measured with the Multidimensional Alcohol Craving Scale (MACS). The risk of relapse was measured with the Alcohol Relapse Risk Scale (ARRS) (subscales: stimulus-induced vulnerability (SV), emotionality problems (EP), compulsivity for alcohol (CA), negative expectancy for alcohol (NE), positive expectancy for alcohol (PE), insight into mental condition (IM)).
Results: Two-step cluster analysis was performed with the six subscales of the ARRS as predictor variables. A two-cluster solution was found, in which SV proved to be the most important predictor. Independent sample t-tests for the two clusters revealed significant between-cluster differences on all subscales except for 'lack of negative expectancy for alcohol' ($p \geq 0.001$). Independent sample t-tests and Chi-square tests were performed to compare the two clusters on the basis of age, sex, the severity of AUD, craving and anxiety. Significant differences were found in almost all factors except for age, sex and the 'rapidity of reinstatement of withdrawal symptoms following abstinence' subscale of the SAD-Q ($p \geq 0.01$).
Conclusions: The first cluster with more defined signs for the risk of relapse was characterised by more severe AUD, craving, state and trait anxiety compared to the second cluster with milder signs for the risk of relapse. These results suggest that the risk of relapse is a complex phenomenon, which can be identified through the evaluation of several different factors, which may influence treatment choices.

Effect of CYP2C19*17 gene polymorphism on plasma levels of diazepam and nordiazepam in Turkish patients with Alcohol Withdrawal Syndrome

S. Özkan-Kotiloğlu[1,2*], D. Kaya-Akyüzlü[2], M. A. Yıldırım[2], M. Danışman[3], C. Bozmaoğlu[2], K. C. Tok[2], M. Gümüştaş[2], I. Özgür-İlhan[4] and S. Süzen[5]

[1]Molecular Biology and Genetics, Kırşehir Ahi Evran University, Kırşehir; [2]Institute of Forensic Sciences, Ankara University; [3]AMATEM Clinic, Ankara Training and Research Hospital; [4]Department of Mental Health and Diseases and [5]Department of Pharmaceutical Toxicology, Ankara University, Ankara, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.637

Introduction: Alcohol withdrawal syndrome (AWS) is not a common medical condition in general population however it affects patients with alcohol use disorder (AUD) and causes severe complications when diagnosed late or left untreated. Diazepam is a benzodiazepine, which is used to treat various diseases such as insomnia, anxiety, muscle spasm, pain and AWS. Compared to other benzodiazepines, diazepam is more efficient to prevent delirium and decrease withdrawal due to its long half-life. Diazepam is metabolised to its main metabolite nordiazepam with the enzymes expressed by *CYP2C19* and *CYP3A4* genes. It has been reported that metabolic activity of the enzymes encoded by *CYP2C19* gene may be varied due to genetic polymorphisms leading a change in the efficiency of treatment via effecting the plasma level of drugs metabolised by *CYP2C19*.
Objectives: The aim of this study is to investigate whether *CYP2C19*17* gene polymorphism has an impact on plasma levels of diazepam and nordiazepam in the Turkish patients with AWS and under oral diazepam treatment.
Methods: The study included 50 male patients who were in withdrawal state and taking diazepam therapy. *CYP2C19*17* polymorphism was determined by PCR-RFLP method. Plasma levels of diazepam (DZP) and nordiazepam (NDZP) were detected by HPLC.
Results: Genotype frequencies were calculated as 66% for CC, 30% for CT and 4% for TT. Dose-normalized DZP and dose-normalized NDZP values were 0.049 µg/ml per mg/day and 0,056 µg/ml per mg/day, respectively. No statistical significance was observed in the levels of normalized DZP and NDZP when CC and CT+TT genotypes were compared (p= 0.073 and p=0.282, respectively).
Conclusions: The effect of CYP2C19*17 polymorphism on the plasma levels of DZP and NDZP following long term oral diazepam to treat patients with AWS was determined for the first time. With the help of current study, first data on Turkish population was obtained and may be useful for personalized therapy in the future.
This study was supported by Scientific and Technological Research Council of Turkey (TUBITAK) under the Grant Number 121C441. The authors thank to TUBITAK for their supports.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.638

Introduction: The consumption of alcohol, cannabis, cocaine, or heroin causes alterations in the central nervous system, affecting mood, perception, and behaviour. Despite the harmful effects of these substances, they remain widely used. Younger individuals tend to consume cannabis and cocaine, while older adults more commonly use alcohol and prescription medications. Ageing brings

changes in consumption patterns and has both physical and mental health consequences
Objectives: This study aims to analyze how age influences the clinical characteristics of patients with Substance Use Disorder (SUD), comparing differences between older and younger users.
Methods: A total of 297 SUD patients participated in this study. They were divided into two groups: those aged 55 and older (G1) n= 88, and those younger than 55 (G2) n= 209. The SF-36 questionnaire was used to assess quality of life, the BIS-11 for impulsivity, the ASRS v1.1 for ADHD, the STAI-R for anxiety, and the AQ for autistic traits. All participants provided informed consent, and the study adhered to ethical guidelines.
Results: G1 showed better social functioning (SF-36) but a significant physical decline compared to G2. G1 also demonstrated lower levels of impulsivity (BIS-11), aggression, anxiety (STAI-R), and ADHD symptoms (ASRS), though higher autistic traits (AQ) were observed in G1.
Conclusions: Ageing reduces impulsivity, aggression, anxiety, and ADHD symptoms in individuals with SUD, but worsens physical health and may increase social isolation and autistic traits. These findings underscore the need to adapt SUD treatments according to age, addressing both physical and psychosocial challenges specific to each group.

Can temperament dimensions predict treatment outcome in inpatients with substance use disorders?

E. Santens[1,2*], E. Dierckx[3,4], G. Dom[2] and L. Claes[2,5]

[1]Addiction Psychiatry, Alexian Psychiatric Hospital, Tienen; [2]Faculty of Medicine and Health Sciences, University of Antwerp, Antwerp; [3]Developmental and Life Span Psychology, Vrije Universiteit Brussel, Brussels; [4]Alexian Psychiatric Hospital, Tienen and [5]Faculty of Psychology and Educational Science, KU Leuven, Leuven, Belgium
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.639

Introduction: Substance use disorders are among the leading causes of morbidity and mortality worldwide. SUDs are highly comorbid with other mental health disorders. Given this comorbidity, a transdiagnostic view on treatment, seems appropriate. Within such a transdiagnostic perspective, treatment outcome can be described as a decrease in comorbid clinical symptomatology and not merely in terms of abstinence/relapse in substance use. A promising transdiagnostic factor within the RDoC framework is temperament, more specifically reactive and regulative temperament. According to the dual pathways model, psychopathology arises from an imbalance between two complementary neurobiological systems: the bottom-up reactivity system in terms of behavioral inhibition (BIS) and behavioral activation (BAS) (reactive temperament) and the top-down regulation in terms of Effortful Control (EC) (regulative temperament).
Objectives: We want to investigate whether reactive (BIS/BAS) and regulative temperament (EC) are associated with treatment outcome in terms of a decrease in clinical symptomatology in a sample of adult inpatients with a SUD. When these temperamental factors turn out to be significant predictors of clinical symptomatology, treatment interventions targeting reactivity (high BAS or BIS level) or aiming at strengthening EC could possibly result in better treatment outcomes for patients with SUDs and comorbid disorders.
Methods: The sample consisted of 612 inpatients with a SUD ((76,5% males, mean age 42,9 years) admitted at a specialized treatment unit for addiction. At the start of the treatment (pre) self-report questionnaires were administered to assess the reactive temperament dimensions (the Behavioral Inhibition/Behavioral Activation System Scales), the regulative temperament dimension (the Effortful Control Scale from the Adult Temperament Questionnaire) and clinical symptomatology (Symptom-Checklist-90-Revised, SCL-90-R). At discharge, the SCL-90-R was administered again to assess treatment effectiveness (post).
Results: Paired sample t-test showed significant decreases between pre- and posttreatment symptom scores indicating that treatment was effective in decreasing symptomatology. A hierarchical regression analysis showed that higher levels of EC were associated with a stronger decrease in levels of psychological symptoms and that higher levels of BIS were associated with a lower decrease. There was however no moderating role of EC in the relation between reactive temperamental dimensions and treatment outcome.
Conclusions: We found that reactive and regulative temperament could predict psychological symptomatology after a residential treatment period of 8 weeks in a specialized addiction unit. These results point out that interventions aiming at either strengthening EC or lowering anxiety (BIS) could possibly result in better treatment outcomes for patients with SUDs their comorbid disorders.

Emotional Dysregulation, Impulsivity, and Interoceptive Awareness in Individuals with Alcohol Use Disorder

F. Seven[1] and M. B. Sönmez[2*]

[1]Psychiatry, Edirne Uzunköprü State Hospital and [2]Psychiatry, Trakya University School of Medicine, Edirne, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.640

Introduction: Impairment in emotion regulation and impulsivity are components of addiction-related mechanisms. The ability to perceive the internal state of the body is known as interoceptive awareness (IA). Impaired IA is believed to contribute to the development and progression of alcohol use disorder (AUD). IA is considered to have two dimensions: interoceptive accuracy (IAc), which measures precise monitoring of bodily sensations, and interoceptive sensibility (IS), which reflects the subjective experience of these sensations. Traits associated with alcohol use vulnerability, such as emotional dysregulation and impulsivity, may also be linked to IA.
Objectives: Our objective was to compare emotional dysregulation, impulsivity, IAc, and IS levels between abstinent patients with AUD and healthy controls. Additionally, we aimed to investigate potential associations between the dimensions of IA and emotional dysregulation and impulsivity.
Methods: The study included 52 abstinent patients with AUD and 52 healthy control subjects. Of the participants, 92.3% (n=48) in each group were male, and 7.7% (n=4) were female. Emotional dysregulation was assessed using the 16-item Difficulties in Emotion Regulation Scale (DERS-16), and impulsivity was measured

using the Barratt Impulsiveness Scale 11 (BIS-11). IAc was evaluated using the heart rate tracking task, which assessed participants' awareness of their own heartbeat by comparing the number of heartbeats they perceived with an objective heart rate measurement. IS was measured using the Multidimensional Assessment of Interoceptive Awareness Version 2 (MAIA-2). The study included patients who had completed detoxification and been abstinent for at least three weeks while participating in or undergoing a 28-day abstinence-based inpatient treatment program.
Results: Individuals with AUD scored significantly higher on self-reported measures of emotional dysregulation (AUD group: 41.50 ± 17.66; control group: 31.19 ± 8.93; $p < 0.001$, $F = 14.106$) and impulsivity (AUD group: 61.63 ± 12.30; control group: 53.06 ± 7.50; $p < 0.001$, $F = 17.828$), and significantly lower on the heart rate tracking task (IAc) (AUD group: 0.65 ± 0.15; control group: 0.84 ± 0.13; $p < 0.001$, $F = 43.615$). No significant difference was found in self-reported IS scores (AUD group: 114.06 ± 21.38; control group: 113.37 ± 13.52; $p = 0.844$, $F = 0.039$). There was a significant correlation between emotion dysregulation and impulsivity scores ($r = 0.633$, $p < 0.001$). IAc and IS scores showed significant negative correlations with emotional dysregulation scores ($r = -0.243$, $p = 0.013$; $r = -0.425$, $p < 0.001$, respectively) and impulsivity scores ($r = -0.204$, $p = 0.038$; $r = -0.416$, $p < 0.001$, respectively).
Conclusions: Our findings support the hypothesis that emotional dysregulation and impulsivity, which are linked to the development and progression of AUD, are associated with interoceptive processes.

Factors affecting anxiety in patients with multiple sclerosis

N. Ben Hamed[1]*, K. Mahfoudh[1], A. Aissa[1], A. Souissi[2] and R. Jomli[1]

[1]psychiatry A , razi hospital and [2]neurology department , LR18SP03 and Clinical Investigation Center Neurosciences and Mental Health - university hospital center Razi, Manouba , Tunisia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.641

Introduction: Anxiety is a common and often debilitating condition in individuals with Multiple Sclerosis (MS), significantly affecting their quality of life. The challenges associated with managing MS symptoms and the potential for disability can contribute to increased levels of psychological distress.
Objectives: The aim of our study was to determine the prevalence of anxiety and identify the its associated factors.
Methods: A cross-sectional study was conducted in the neurology department of Razi University Hospital (Tunisia) between October 2023 and June 2024. Patients with a diagnosis of MS based on the 2017 McDonald criteria were recruited, excluding those with active disease relapses. Participants completed questionnaires covering sociodemographic data, medical history, clinical and radiological characteristics, disability status, and psychological symptoms. Depression, anxiety and stress were assessed using the DASS-21 scale. Insomnia was evaluated using the Pittsburgh Sleep Quality Index (PSQI). Data analysis was performed using SPSS version 26.
Results: A total of 83 patients with MS were recruited, with ages ranging from 19 to 66 years. The study population had a predominantly female sex ratio of 3.4. The majority of participants (75.9%) were from urban areas, and 74.7% had a university-level education. Moreover, 49.1% were married, and 60.2% were employed. Regarding medical history, 40.3% had a comorbid condition, and 30.1% had a psychiatric history. The mean age at disease onset was 26 ± 10 years, and the most common clinical presentations were sensory and pyramidal symptoms.
The median time since the last relapse in our sample was 24 months .In our sample, first-line treatments (interferon, glatiramer acetate, teriflunomide, dimethyl fumarate) were prescribed to 27.7% of patients. Second-line treatments (natalizumab, ocrelizumab, fingolimod) were prescribed to 69.9% of patients
In our study, the prevalence of anxiety was 55.4%. In our population , 26.5% of the patients had severe anxiety. A significant association was found between anxiety and female gender ($p=0.02$), stress ($p<0.001$), and insomnia ($p=0.003$).
Conclusions: The findings indicate that anxiety is a considerable concern for individuals with MS. Addressing this mental health issue is essential for healthcare providers to offer effective support. By prioritizing mental health, we can enhance the overall well-being of individuals living with MS and improve their quality of life.

Influence of Demographic and Socioeconomic Factors on Mental Exhaustion and Social Exclusion in the Workplace

E. D. Cindik-Herbrueggen

Psychiatry, Neuro-Psychiatric Center, München, Germany
doi: 10.1192/j.eurpsy.2025.642

Introduction: Mental exhaustion and social exclusion are significant challenges in the workplace that can negatively affect well-being and job performance. Various demographic and socioeconomic factors may differently impact these phenomena. This study examines how age, gender, marital status, educational level, number of children, employment status, origin, and generation influence mental exhaustion and social exclusion in the workplace.
Objectives: The primary objective of this investigation is to explore and analyze the relationships between demographic and socioeconomic factors and the dimensions of mental exhaustion and social exclusion. The study aims to identify differences and interactions among various factors, as well as to gain a deeper understanding of their impact on workplace well-being.
Methods: The research was conducted by Dr. Elif Cindik, psychologist Merve Gediz, and psychology student Dicle Mutlu. A total of 73 participants were surveyed. Standardized questionnaires

were used to measure mental exhaustion and social exclusion, and demographic as well as socioeconomic data were also collected. The analysis employed statistical methods such as Analysis of Variance (ANOVA), Post-Hoc Tests, Regression, and Pearson Correlation Tests to examine the relationships between the variables.
Results: The tests revealed significant results in the various research areas mentioned above.
Conclusions: The study highlights the complex relationships between the examined demographic and socioeconomic factors and the dimensions of mental exhaustion and social exclusion. Significantly important differences were found among older age groups, single participants, individuals with lower educational levels, and various income levels. Further research is needed to explore the causes of these differences in more detail and to develop potential intervention strategies. The findings provide valuable insights for measures aimed at improving workplace well-being.

EPP359

Differential impact of comorbid depression and adjustment disorder on self-compassion in patients with anxiety disorders

K.-U. Lee[1]*, H.-S. Chun[1] and S. Kim[1]

[1]Psychiatry, Uijeongbu St. Mayr's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Korea, Republic Of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.643

Introduction: The capacity of self-compassion may contribute to the development or protection of psychiatric disorders.
Objectives: This study aimed to examine the relationship between self-compassion and psychopathologies in anxiety disorders and to identify the impact of comorbid depression on self-compassion.
Methods: Patients diagnosed with anxiety disorders were recruited from the outpatient clinic of the Catholic University of Korea. Psychiatric diagnoses were established through interviews based on DSM-5 criteria, conducted by an experienced psychiatrist. Demographic data were collected, and clinical status was evaluated using the Clinical Global Impression (CGI) scale. The severity of anxiety, depression, somatic symptoms, hypochondriasis, and self-compassion were assessed using the Generalized Anxiety Disorder-7 (GAD-7), Patient Health Questionnaire-9 (PHQ-9), Patient Health Questionnaire-15 (PHQ-15), Illness Attitude Scale (IAS), Cyberchondria Severity Scale (CSS-12), and Self-Compassion Scale (SCS), respectively.
Results: The study included 121 participants with a mean age of 48.65 years (SD = 10.10), ranging from 20 to 70 years. The majority of the participants were female, comprising 91 (75.2%) of the sample, while 30 (24.8%) were male. A significant inverse relationship was observed between self-compassion (SCS total) and measures of general psychopathologies and hypochondriasis: PHQ-9 ($r = -0.366$, $p < 0.001$), GAD-7 ($r = -0.348$, $p < 0.001$), PHQ-15 ($r = -0.349$, $p < 0.001$), IAS ($r = -0.293$, $p < 0.005$), and CSS-12 ($r = -0.208$, $p < 0.05$). Also, strong negative correlations were found with all psychopathology measures, showing that higher negative self-compassion is significantly related to greater psychopathology: PHQ-9 ($r = -0.479$, $p < 0.001$), GAD-7 ($r = -0.423$, $p < 0.001$), PHQ-15 ($r = -0.364$, $p < 0.001$), IAS ($r = -0.374$, $p < 0.001$) and CSS-12 ($r = -0.362$, $p < 0.001$). An ANCOVA was conducted to assess group differences in self-compassion subscales among patients with anxiety disorders (N = 71), comorbid depressive and adjustment disorders (N = 22), and comorbid somatic symptom and related disorders (N = 25). The results showed a significant difference in the isolation subscale across the groups ($F = 4.636$, $p = .012$).
Conclusions: The findings underscore the role of self-compassion in moderating psychopathology severity in anxiety disorders, suggesting that interventions targeting negative self-compassion may help mitigate emotional and physical symptoms in these patients

Theory of Mind Deficits in Individuals at Risk and Early Onset of Bipolar Disorder

E. Cesim[1]*, M. Demir[1], M. Eyuboglu[1], Y. E. Turan[1], Ö. İlhan[1], S. Uzman Özbek[2], B. Yalınçetin[1] and E. Bora[1,2]

[1]Department of Neurosciences and [2]Department of Psychiatry, Dokuz Eylül University, İzmir, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.645

Introduction: Impairments in theory of mind, which influence the ability to accurately perceive and comprehend the mental states of oneself and others, play a pivotal role in psychiatric diseases. Understanding these cognitive aspects is crucial for developing targeted interventions and improving overall patient outcomes.
Objectives: The purpose of this study is to examine theory of mind in individuals at risk for bipolar disorder and in the early stages of the disorder.
Methods: Sixty-two individuals with first-episode bipolar disorder (FE-BD) (mean age 21.92±4.58), seventy-eight individuals at ultra-high risk for bipolar disorder (UHR-BD) (mean age 20.5±3.93), and seventy-four healthy controls (HC) (mean age 23.36±5.28) were included in this study. The Hinting Task (HT) and the Reading the Mind in the Eyes Test (RMET) were applied to assess theory of mind.
Results: The groups differed significantly in RMET positive ($F(2\text{-}200)=5.087$, $p=0.007$), neutral ($F(2\text{-}200)=4.777$, $p=0.009$) subscores, and total score ($F(2\text{-}200)=11.267$, $p=0.000$). Similarly, differences were found among the groups in terms of hypomentalization ($F(2\text{-}174)=5.251$, $p=0.006$), hypermentalization ($F(2\text{-}174)=4.786$, $p=0.009$), and total scores ($F(2\text{-}174)=13.292$, $p=0.000$) on the

Hinting Task. No significant differences were observed in RMET negative scores among the groups (p>0.05). Both the FE-BD and UHR-BD groups exhibited significantly lower scores than the healthy controls across positive, neutral, and total RMET scores, as well as in total Hinting Task scores (p<0.05). Hypomentalization and hypermentalization errors were higher in the FE-BD and UHR-BD groups than in the HC group (p<0.05).
Conclusions: The results revealed significant differences in theory of mind performance between groups, including RMET scores and Hinting Task results. Individuals with first episode bipolar disorder (FE-BD) and those at ultra high risk for bipolar disorder (UHR-BD) consistently scored lower than healthy controls, emphasizing the need for targeted, early interventions in theory of mind and related cognitive processes. Future studies investigating clinical and neurobiological correlates of theory of mind across different stages of bipolar disorder are needed.

Thyroid Function Paremeters in Drug Naive, First Episode Mania: Are Thyroid Dysfunctions Present at The Onset of the Illness ? A Case Control Study

F. Çınar[1]*, Ö. Bayırlı[1] and R. Tekdemir[1]

[1]Psychiatry, Selcuk University, Konya, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.646
Introduction: Bipolar disorder features recurrent episodes of mania, hypomania, and depression, with first-episode mania serving as an early indicator. The biological and psychological factors involved are not fully understood. Thyroid hormones play a vital role in brain metabolism, and their dysregulation has been linked to mood disorders, indicating potential abnormalities during manic episodes.
Objectives: This study aims to evaluate the presence of thyroid dysfunction in drug-naive patients experiencing their first episode of mania compared to a healty control group.
Methods: This study included forty-eight drug-naive patients diagnosed with first-episode mania, who were hospitalized for treatment, and a control group of forty-eight healthy individuals. The healthy control group was matched for age and sex and had no history of psychiatric illness or treatment. There were no physical illnesses in either group. Symptom severity was assessed using the Brief Psychiatric Rating Scale (BPRS) and the Young Mania Rating Scale (YMRS). Serum T3, T4, TSH levels were measured in both groups. The study protocol was approved by the Local Ethics Committee of Selcuk Üniversity.
Results: There were no differences in sex and age distribution between the groups. In the patient group, 54.2% (n=26) were female, with a mean age of 24.98 (±7.38). Additionally, 16.7% (n=8) had a history of depression, and 49.7% (n=23) exhibited psychotic features. Analysis of serum TSH, T3, T4, and the T3/T4 ratio showed no significant differences between groups (TSH: t=-0.466, p=0.642; T3: t=1.258, p=0.212; T4: t=-0.874, p=0.382; T3/T4: t=-1.291, p=0.200). T3 levels were higher in males overall and in the control group (t=-3.000, p=0.004; t=-3.753, p<0.001), but not in the patient group (p>0.05). Among patients, T4 levels were significantly higher in those with psychotic features (t=-2.410, p=0.020). Correlation analysis showed no significant relationships between thyroid function tests and clinical variables.
Conclusions: This study found no significant differences in thyroid function parameters between drug-naive patients with first-episode mania and healthy controls, suggesting that thyroid dysfunction may not be present at the onset of mania. While T4 levels were higher in patients with psychotic features, overall results indicate that thyroid abnormalities do not play a critical role in the immediate presentation of this disorder. These findings highlight the need for further research to explore the long-term relationship between thyroid function and bipolar disorder.

Assessing language abnormalities using NLP methods in speech excerpts of individuals at ultra-high risk for bipolar disorder

E. Kizilay[1]*, B. Arslan[1] and E. Bora[1,2,3]

[1]Department of Neurosciences; [2]Department of Psychiatry, Dokuz Eylul University, Izmir, Türkiye and [3]Department of Psychiatry, University of Melbourne and Melbourne Health, Melbourne , Australia

doi: 10.1192/j.eurpsy.2025.647

Introduction: Detection for individuals at ultra-high risk for bipolar disorder (UHR-BD) is crucial due to the exploration of potential biomarkers at the early stages of bipolar disorder, including language abnormalities. Formal thought disorder (FTD) is an important symptom that can be observed in BD, which may be mildly noticeable during the early stages of the disease. Automated methods have demonstrated the ability to evaluate FTD in psychotic disorders and can also be employed to evaluate FTD in the speech of individuals at UHR-BD.
Objectives: This study aimed to investigate the differences in language between UHR-BD and healthy controls (HC) using natural language processing (NLP) methods.
Methods: We collected speech samples from 20 individuals at UHR-BD and 20 HC during descriptions of eight Thematic Apperception Test (TAT) pictures, which were then manually transcribed. After transcribing the text, word2vec was used to convert it into vectors. The semantic similarity between words was calculated using a moving window approach to windows of words sized 5-10. Finally, the mean and variance of similarities were determined.
Results: The variances of similarities in the windows of 5 to 9 were increased in UHR-BD (p=0.004, p=0.005, p=0.01, p=0.02, and p=0.037, respectively). There was no significant difference regarding the mean similarity.
Conclusions: To our knowledge, this is the first study to evaluate language with NLP methods in individuals at UHR-BD. Our findings showed that the variance of semantic similarity differed between the two groups. This indicates NLP methods may be used in the UHR-BD group to detect FTD.

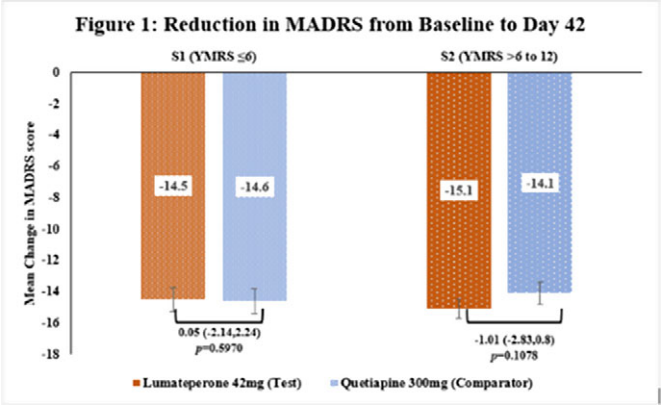
Introduction: Lumateperone, an atypical antipsychotic drug approved for Bipolar II depression in 2021, has a dual mechanism of action by combination of activity at central serotonin (5-HT2A) and dopamine (D2) receptors.



Objectives: This subgroup analysis of an Indian Phase 3 study was conducted to evaluate the efficacy and safety of Lumateperone 42mg compared to Quetiapine 300mg in treatment of Bipolar II depression when stratified based on mixed symptoms assessed via Young Mania Rating Scale (YMRS).

Methods: The phase-III, randomized, multi-centric, assessor-blind, parallel-group, active-controlled, comparative, non-inferiority study included patients with Bipolar II depression with moderate severity having a Montgomery-Asberg depression rating scale (MADRS) score ≥20 and Clinical global impression–bipolar version–severity (CGI-BP-S) score ≥4. The study was conducted after receiving regulatory and ethics committee approvals. The patients were randomized (1:1) to either receive Lumateperone 42mg [Test] or Quetiapine 300mg [Comparator] for 6 weeks. The patients were stratified based on YMRS: Subgroup 1 [S1]: ≤6 and Subgroup 2 [S2]: >6 to 12. For efficacy outcomes MADRS score, CGI-BP-S (total score, depression subscore and overall bipolar illness subscore), and Quality of life enjoyment and satisfaction-short form questionnaire (Q-LES-Q-SF) score were evaluated and for safety outcomes treatment emergent adverse events (TEAEs) were assessed. [Clinical trial registration: CTRI/2023/10/058583]

Results: This subgroup analysis included 235 patients in S1 [Test=109; Comparator=126] and 227 in S2[Test=122; Comparator=105]. The baseline demographic characteristics were comparable in between treatment arms across subgroups. The primary endpoint of reduction in MADRS score from baseline to Day 42 in Test arm was non-inferior to Comparator arm in both subgroups [Figure 1] as the upper 95% CI was below the pre-defined margin of 3.0. The reduction of CGI-BP-S (total score, depression subscore and overall bipolar illness subscore) from Day 14 to Day 42 were comparable in both Test and Comparator arms in both subgroups. The improvement in Q-LES-Q-SF score from baseline to Day 42 were comparable in both Test and Comparator arms in both subgroups. The incidence of TEAEs were similar in both treatment arms [S1: Test=28.4% and Comparator=28.6%; S2: Test=40.2% and Comparator=43.8%] and no serious adverse events were reported.

Image 1:

Figure 1: Reduction in MADRS from Baseline to Day 42

Conclusions: This subgroup analysis demonstrated that Lumateperone 42mg is non-inferior to Quetiapine 300mg in treatment of Bipolar II depression as assessed via MADRS score from baseline to Day 42, irrespective of presence of mixed symptoms and both treatments were found to be well tolerated.

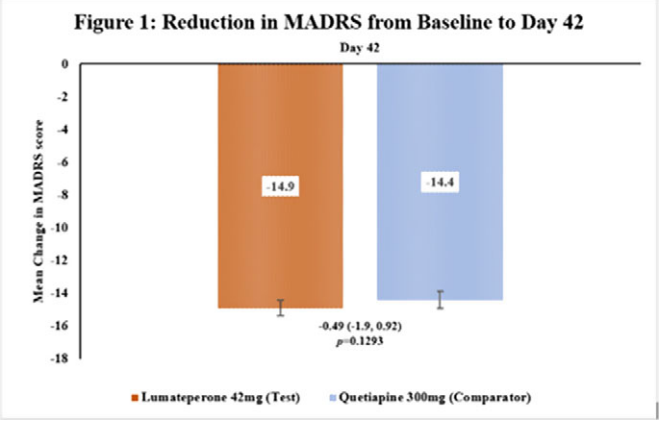
Introduction: Lumateperone, an atypical antipsychotic drug, has a dual mechanism of action by combination of activity at central serotonin (5-HT2A) and dopamine (D2) receptors.
Objectives: This post-hoc analysis of an Indian Phase 3 study was conducted to evaluate the impact of Lumateperone 42mg compared to Quetiapine 300mg on severity of depression assessed via MADRS in patients with Bipolar II depression.
Methods: The phase-III, randomized, multi-centric, assessor-blind, parallel-group, active-controlled, comparative, non-inferiority study included patients with Bipolar II depression with moderate severity having a Montgomery-Asberg depression rating scale (MADRS) score ≥20 and Clinical global impression–bipolar version–severity (CGI-BP-S) score ≥4. The study was conducted after receiving regulatory and ethics committee approvals. The patients were randomized (1:1) to either receive Lumateperone 42mg [Test] or Quetiapine 300mg [Comparator] for 6 weeks. This post-hoc analysis evaluated MADRS total score and individual items from Question 1 to Question 10 i.e. (Q1) Apparent sadness; (Q2) Reported sadness; (Q3) Inner tension; (Q4) Reduced sleep; (Q5) Reduced appetite; (Q6) Concentration difficulties; (Q7) Lassitude; (Q8) Inability to feel; (Q9) Pessimistic thoughts; and (Q10) Suicidal thoughts respectively and for safety outcomes treatment emergent adverse events (TEAEs) were assessed. [Clinical trial registration: CTRI/2023/10/058583]
Results: This subgroup analysis included 462 patients, out of which 231 were in the Test group and 231 in the comparator group. The baseline demographic characteristics were comparable in between treatment arms. The reduction in MADRS score (total and individual items) from baseline to Day 42 in Test arm was comparable to Comparator arm [Figure 1 & 2]. The incidence of TEAEs were similar in both treatment arms [Test: 34.6%; Comparator: 35.5%] and no serious adverse events were reported.

Image 1:



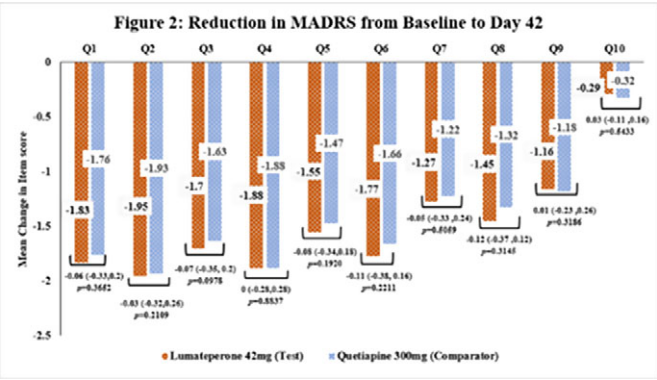


Image 2:

Conclusions: This post-hoc analysis demonstrated that Lumateperone 42mg is comparable to Quetiapine 300mg in treatment of Bipolar II depression as assessed via MADRS score from baseline to Day 42, and both treatments were found to be well tolerated. Hence, Lumateperone can be considered as valuable treatment option in management of Bipolar II depression.

Characteristics of Children and Adolescents with High Functioning Autism and Optimal Outcome

Z. Ayaslan[1]*, Ç. Ermiş[2] and H. B. Baykara[3]

[1]Department of Child and Adolescent Psychiatry, SBU Dr. Behcet Uz Pediatrıc Diseases And Surgery Trainıng And Research Hospital, Izmir, Türkiye; [2]Department of Child and Adolescent Psychiatry, Queen Silvia Children's Hospital, Gothenburg, Sweden and [3]Department of Child and Adolescent Psychiatry, Dokuz Eylul University, Izmir, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.651

Introduction: In general, Autism spectrum disorders (ASDs) are considered lifelong disorders but recent data suggests that after treatment, symptomatic improvement and even loss of diagnosis can be achieved in some cases. Although there is not yet a consensus, the term 'optimal outcome' is generally used for this group of children. Literature on optimal outcome contributes in evaluating treatment efficacy and in identifying factors influencing good prognosis.
Objectives: The aim of this study is to describe a group of children who achieved optimal outcome and compare sociodemographic and clinical features with the cases still being followed up with the diagnosis of High Functioning Autism (HFA).
Methods: This study consists of 60 cases aged 4-18 years who were diagnosed with Autism Spectrum Disorder according to DSM-IV (before 2013) or DSM-5 criteria by clinicians in Dokuz Eylul University Faculty of Medinice Hospital Child and Adolescent Psychiatry Department Outpatient Clinic and during follow-up considered optimal outcome and cases who still meet the diagnosis of High Functioning Autism. The necessary data were collected through retrospective examination of the medical records and during clinical interviews. Comorbid psychopathologies were assessed with the Schedule for Affective Disorders and Schizophrenia for School-Age Children-Present and Lifetime version (K-SADS-PL) semi-structured interview. Childhood Autism Rating Scale (CARS) were applied to evaluate the severity of the symptoms. Intelligence and developmental test results were recorded if available in the medical records for cognitive assessment.
Results: The optimal outcome (OO) group was diagnosed and started special education at a significantly earlier age than the HFA group (p=0.001). The duration of pre-school education was also significantly higher in the optimal outcome group (p=0,023). Symptom severity assessed by CARS at both the time of diagnosis and the current situation was significantly lower in the optimal outcome group (p<0.001, p<0.001). There was no significant difference between the two groups in terms of early verbalization skills and WISC-R scores.
Conclusions: In our study we defined a group of children who lost their diagnosis of autism after special education. Early diagnosis and initiation of special education and less severe ASD symptoms at the time of diagnosis were found to be important factors contributing to optimal outcome.

Biomarkers of oxidative stress and inflammation in urine samples of extremely preterm newborns and risk for autism at corrected-age 24 months

T. Bollain Muñoz[1]*, J. Merchán-Naranjo[1,2,3,4], B. Almansa[5], C. Chafer[5], M. Vento[5], D. Blanco-Bravo[2,3,6], A. García-Blanco[5] and L. Pina-Camacho[1,2,3,4]

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.652

Introduction: Extremely preterm birth (defined as birth before 28 weeks' gestational age) has been associated with an increased risk of developing autism spectrum disorder (ASD) in infancy. The underlying pathophysiological mechanisms driving the emergence of ASD in these children remain unknown, although growing evidence suggests that oxidative stress and inflammation play important roles.
Objectives: To detect if urinary protein oxidation could serve as a non-invasive early predictor of ASD risk in extremely preterm newborns.
Methods: In two Spanish cohorts recruited between 2020 and 2022, consisting of 76 extremely preterm newborns, we collected urine samples from birth up to the first week of life (T1 = birth, T2 = 24–72 hours, T3 = day 7) and analyzed biomarkers of oxidative stress and inflammation. We assessed the risk for ASD at a corrected age of 24 months. Using liquid chromatography-mass spectrometry, we measured levels of lipid peroxidation, DNA and protein oxidation metabolites, along with markers of inflammation. We investigated the association between longitudinal urine marker levels and the primary outcome (risk for ASD, defined as an MCHAT-R/F score ≥ 2 at 24 months).
Funding: The study was supported by the Spanish Ministry of Science & Innovation, Instituto de Salud Carlos III (grant numbers PI17/01997, PI18/01352, PI20/01342, PI23/00368); co-financed by ERDF Funds from the European Commission, "A way of making Europe", Fundación Familia Alonso & Fundación Alicia Koplowitz.
Results: Thirty-two of the 76 patients completed the 24-month follow-up period and had samples available from at least two of the three time points. Compared to those with no risk for ASD (n = 21), patients at risk for ASD (n = 11) exhibited significantly lower O-tyrosine levels at birth (d = 1.296, p = .048). Moreover, O-tyrosine levels increased significantly over time in at-risk patients relative to non-ASD risk patients from birth to day 7 (p = .032), suggesting protein damage due to significant oxidative stress.
Conclusions: These findings indicate that urinary protein oxidation markers could serve as promising, non-invasive early predictors of ASD risk in extremely preterm newborns.

doi: 10.1192/j.eurpsy.2025.653

Introduction: Autism spectrum disorder (ASD) is linked to synaptic function and plasticity, and cell adhesion molecules play an important role in these processes. Dysfunction of CAMs disrupts synaptic activity and plasticity processes.

Objectives: This study aims to investigate NCAM1, NRXN1, NLGN4, and N-cadherin levels in the peripheral circulation of individuals with ASD, their siblings, and healthy controls without any psychiatric diagnosis. We also investigate how these biochemical parameters affect autism severity, behavioral problems, and autistic traits in siblings.

Methods: The patient group of the study consisted of 41 children aged between 18-72 months who were diagnosed with ASD according to DSM-5 diagnostic criteria and 41 healthy siblings aged between 24-72 months of the child diagnosed with ASD (Control Group 1). We assessed the severity of ASD symptoms in participants diagnosed with ASD using the Childhood Autism Rating Scale and the Autism Behavior Checklist. Control Group 2 consisted of 41 children aged between 18-72 months who did not have ASD or any other psychiatric disorder or physical illness (Control Group 2). The parents of the patient group completed the Autism Spectrum Screening Scale for the sibling of the individual diagnosed with ASD. We determined serum NCAM1, NRXN1, NLGN4, and N-Cadherin levels in peripheral blood samples by ELISA.

Results: There was no statistically significant difference in NCAM1, NRXN1, NLGN4, and N-Cadherin levels between all three study groups. There was a statistically significant positive correlation between NCAM1 and NRXN1 levels in the ASD group.

Conclusions: In this study, we investigated the serum levels of NCAM1, NRXN1, NLGN4, and N-Cadherin, which are cell adhesion molecules potentially associated with ASD etiology. Although the proteins we investigated were expressed differently between the groups, we did not find any statistically significant difference between ASD patients, healthy siblings, and healthy groups. More research is needed in this area.

doi: 10.1192/j.eurpsy.2025.654

Introduction: Autism spectrum disorder (ASD) is characterized by communication challenges, particularly in non-verbal aspects such as facial expressions.Research in this area is limited due to the lack of accurate methodologies. Existing literature generally agrees that individuals with ASD often show a disconnect between verbal communication and emotional expression, with facial expressions being diminished or inappropriate. Most studies have relied on ratings by highly trained observers, which can reduce accuracy and introduce biases, such as confirmation bias.

Objectives: Our goal was to create a model for capturing and analyzing facial expressions using computer algorithms and assess its effectiveness in identifying individuals with ASD.

Methods: The study involved 100 participants, divided into two groups based on ASD diagnosis. The ASD group included 73 individuals, 51 (69.8%) of whom were male, while the control group comprised 27 participants, with 16 (59.2%) being male. ASD diagnoses were made by a specialist child and adolescent psychiatrist using developmental history and mental state examinations, confirmed with the ADOS-2 protocol. In the control group, ASD was ruled out using the same protocol. A significant age difference was found between the ASD group (mean age: 14 years; 95% CI: 13.5-14.5) and the control group (mean age: 16.3 years; 95% CI: 15.2-17.5), according to the Mann-Whitney U test.

All participants completed three tasks: a semi-structured conversation, recognizing facial expressions displayed on a screen, and imitating these expressions. Throughout the tasks, participants' faces were recorded using five cameras positioned around them. Faces were then detected in the images using a sliding window algorithm in a multi-resolution representation of the Gaussian pyramid utilizing a linear classifier based on the Support Vector Machine (SVM) with a classical Histogram of Oriented Gradients (HOG) descriptor. An Ensemble of Regression Trees was applied to these detected faces to model facial landmarks in each frame. Using these landmarks, anthropometric distances and proportions were calculated, which were then used to train the SVM classifier.

Results: The obtained model was able to predict the diagnosis of ASD in the study population with almost 100% accuracy. The mean difference between the probability of the correct class and the probability of the incorrect class determined by the SVM on the test set was 56%.

Conclusions: This method of facial expression analysis using an SVM classifier shows potential as a tool for diagnosing ASD. The technique could be applied using smartphones. However, further research is needed to evaluate its clinical viability, particularly when using non-standard devices. These findings also support the hypothesis that individuals with ASD display facial expressions significantly differently from neurotypical individuals.

Self-harm, early emotional neglect and alexithymia in young Italian help seekers

S. Mammarella[1]*, L. Giusti[1], S. Del Vecchio[1], A. Salza[1], M. Casacchia[1] and R. Roncone[1]

[1]Department of Life, Health and Environmental Sciences, University of L'Aquila, L'Aquila, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.655

Introduction: Recent studies showed that non-suicidal Self-Injury (NSSI) is a transdiagnostic behavior with multiple functions and motivational factors. More specifically, two key functions have been identified: the first is an interpersonal function (hurting/punishing others, influencing others' behavior); the second involves personal goals (emotions regulation, dissociation, self-punishment). Some distal factors may contribute to the onset of this behavior (e.g., childhood abuse, emotional neglect), resulting in emotional dysregulation and alexithymia. Alexithymia, also called emotional blindness, a coping strategy to reduce emotional pain following trauma traumatic life events, emerged as a predictor of NSSI.
Objectives: The study aimed to investigate in a sample of young Italian help seekers referred to an early intervention service and a university counseling and consultation service (1) the prevalence of NSSI behaviors; (2) their correlation to early traumatic life experiences and alexithymia symptoms.
Methods: From March 2023, the young adults participating in this study filled a standardized battery (through a QR code). In this preliminary analysis, only data concerning the Deliberate Self-Harm Inventory (DSHI), Childhood Trauma Questionnaire – Short Form (CTQ-SF), and the Toronto Alexithymia Scale (TAS – 20) were considered.
Results: Nowadays, 73 young adults participated in the study (60% women; mean age 26 years, SD 4.2). A third of the sample reported NSSI behavior lifetime, with a higher distribution among women ($\chi 2$= 9.425 p=0.002). By comparing the NSSI and No-NSSI groups, only the emotional neglect dimension exceed the clinical cut-off even if statistically significant differences emerged in all the early traumatic dimensions, with higher scores in the NSSI group as regard the emotional abuse (F= 18.321; p=0.000), physical abuse (F= 17.556; p=0.000), sexual abuse (F= 5.200; p=0.026), emotional neglect (F= 20.053; p=0.000), physical neglect (F= 12.134; p=0.001), minimization/denial (F= 13.384; p=0.000). The alexithymia symptoms, assessed with the TAS-20 scale, the NSSI group showed higher scores with a statistically significant difference compared to the No-NSSI group (F= 15.842; p=0.000) and, specifically, in the "*difficulty describing feelings*" (F= 10.351; p=0.002) and "*difficulty in identifying emotions*" (F= 13.543; p=0.000).
Conclusions: According to the social neuroscience model, these preliminary results suggested that young adults that practice self-harm behaviors may have experienced early emotional neglect, determining a vulnerability to recognize and regulate emotions in response to stressful events. It is therefore crucial to assess and monitor this behavior in all young people help seekers from mental health services, concerning the history of traumatic events and emotional difficulties, to plan personalized evidence-based interventions.

Association between substance use and sleep disturbances among adolescents: Systematic review and meta-analysis

D. Phiri[1]*, V. L. Amelia[1,2], M. Muslih[1,3], L. P. Dlamini[1], M.-H. Chung[1,4] and P.-C. Chang[1]

[1]School of Nursing, College of Nursing, Taipei Medical University, Taipei, Taiwan, Province of China; [2]Nursing Department, Faculty of Health sciences, Universitas Muhammadiyah Purwokerto, Purwokerto; [3]School of Nursing, Faculty of Health Sciences, University of Muhammadiyah Malang, Malang, Indonesia and [4]Department of Nursing, Taipei Medical University Shuang Ho Hospital, Taipei, Taiwan, Province of China
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.656

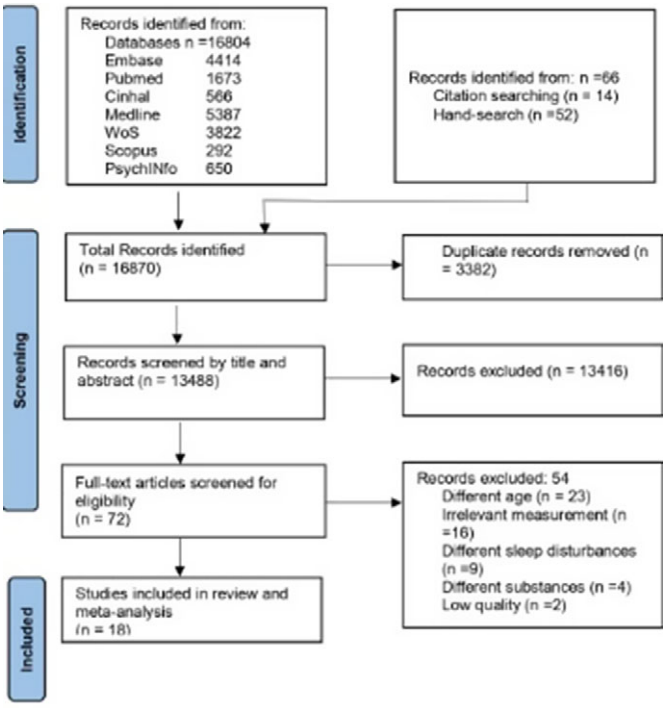
Introduction: Substance use is a major factor contributing to sleep disturbances in adolescents, whose developing brains are especially vulnerable. The previous studies have primarily focused on adults or individual substances.
Objectives: This meta-analysis examined the overall association between substance use and sleep disturbances in adolescents.
Methods: Relevant studies were systematically searched across multiple databases, including CINHAL (via EBSCOHOST), PubMed, Scopus, Ovid Medline, Embase, PsychINFO (via EBSCOHOST), and Web of Science, from inception until October 2021. A random-effects model was employed to calculate pooled Odds Ratios (OR) with 95% confidence intervals (CIs). Forest plots and Cochran's Q statistic p values were utilized to assess heterogeneity among the studies. Subgroup and meta-regression analyses were conducted to compare groups and identify sources of heterogeneity. Study quality was evaluated using the Joanna Briggs Institute tool, and sensitivity analysis was performed to test the robustness of the results.
Results: A comprehensive search identified 16,870 studies, of which 18 were included in the review and meta-analysis (Figure 1), published between 1993 and 2021. The studies were of high quality and had a low risk of bias. The results showed that substance use significantly contributes to sleep disturbances in adolescents (OR = 1.70, 95% CI: 1.49–1.94) (Figure2). Alcohol users, coffee drinkers, and smokers were significantly more likely to experience sleep disturbances (OR = 1.77, OR = 1.58; OR = 1.66), while marijuana showed a non-significant association (OR = 1.29) (Table 1). Additionally, alcohol and smoking were significantly associated with insomnia (OR = 1.82, 95% CI: 1.43- 2.33 and OR = 1.75, 95% CI: 1.31-2.33), hypersomnolence (alcohol: OR = 1.46, 95% CI: 1.18-1-81), and sleep-related breathing disorders (S-RBD) (alcohol: OR = 2.29, 95 % CI: 1.53-3.42; smoking: OR = 2.30, 95% CI: 1.23-4.30), with coffee also significantly associated with insomnia (OR = 1.58, 95% CI: 1.30-193). There was considerable heterogeneity among the studies, however, subgroup and meta-regression analysis indicated no statistically significant sources of heterogeneity.

Table 1 Association between individual substance use and sleep disturbances

	n Study	OR	95% CI Lower limit	Upper limit	Q -value	Heterogeneity P-Value	I^2
Alcohol	15	1.77	1.55	2.03	102.21	<0.001	86.30
Coffee	3	1.58	1.30	1.93	6.02	<0.005	66.81
Marijuana	3	1.29	0.78	2.13	24.38	<0.001	91.79
Smoking	15	1.66	1.37	2.01	278.13	<0.001	94.96

OR = Odds Ratio, CI = Confidence Interval

Image 1:



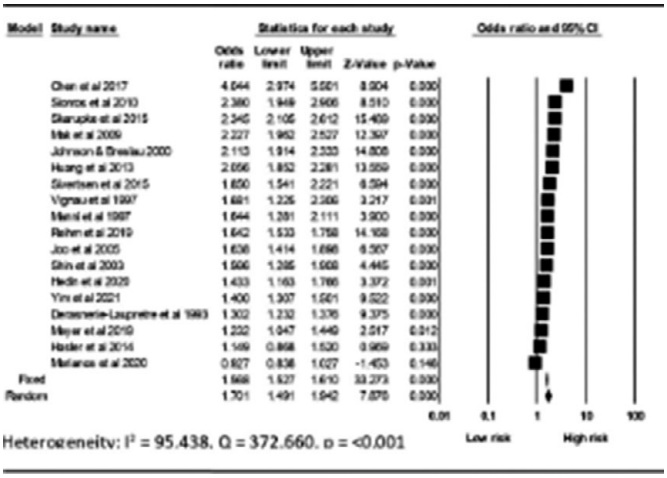


Figure 1: PRISMA Flow Chart

Image 2:

Conclusions: Substance use significantly increases the risk of sleep disturbances in adolescents, with alcohol, coffee, and smoking showing strong associations. Despite the heterogeneity among studies, the findings underscore the need for targeted interventions to mitigate these risks and improve sleep health in this population.

Let's learn about emotions - a school based universal intervention on socio-emotional learning

T. Ståhlberg[1]*, Y. Mori[2], X. Zhang[2], T. Korpilahti-Leino[2], K. Mishina[2], T. Ristkari[2], S. Hinkka-Yli-Salomäki[2], S.-I. Ishikawa[3] and A. Sourander[2,4]

[1]Adolescent psychiatry, Turku university hospital; [2]Research centre for child psychiatry, University of Turku, Turku, Finland; [3]Faculty of Psychology, Doshisha University, Kyoto, Japan and [4]Child psychiatry, Turku university hospital, Turku, Finland

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.657

Introduction: Socio-emotional problems are widely present in school aged children thus interfering with classroom climate and possibly leading to psychopathology. Several universal interventions exist but evidence-based and motivating interventions are still warranted.

Let's learn about emotions was originally developed in Kyoto, Japan. It is based on cognitive behavioral therapy, positive psychology and socio-emotional learning. It is a highly structured program including 12 lessons to be taught in the classroom by teachers. It has been aimed for primary school aged children. This program was translated in Finnish and culturally adapted to be suitable for the Finnish school environment.

Objectives: This study aims to produce an evidence based universal intervention that is feasible for teachers and motivating and inspirational for pupils. The aim is to increase the socio-emotional skills among pupils and teachers. Thus improvenment could be noticed within the individuals as well as in the classroom and school environment.

Methods: In spring 2023 (study 1) the Finnish version of the intervention was taught to each 4th grader in the city of Hyvinkää, Finland. Data was collected from pupils, parents and teachers before and twice after the intervention with Strengths and Difficulties Questionnaire (SDQ) and questionnaires of classroom environment, school safety, bullying, feasibility and satisfaction. A single group pre-post test design was used. Qualitative interviews were carried out for parents, teachers and principals after the intervention. Effectiveness on the intervention will be studied in 2025-2026 in a larger quasi-experimental study.

Results: Altogether 208 pupils and parents participated in the study 1 in Hyvinkää before and after the intervention. The results showed significant improvement in the parent-reported SDQ scores in conduct problems (0.31 points; SD 1.64, p=0-022), hyperactivity (0.37 points; SD 1.36, p=0.001), peer problems (0.19 points; SD 1.09, p=0.036) and impact of difficulties (0.98 points, SD 3.08, p<0.001). No improvement was observed in the pupil report when all pupils were icluded in the analysis. A Pearson correlation test between self-reports and parent-reports for the SDQ total score revealed significant results for both T0 ($r = 0.439$, $p < 0.001$) and T1 ($r = 0.377$, $p < 0.001$). Among the pupils with the top 20% of difficulty scores by SDQ at baseline, significant improvements were observed in the SDQ total score (1.66 points; SD = 4.94, p = 0.046), emotional problems (0.90 points; SD = 2.71, p = 0.049) and impact of difficulties (0.85 points; SD = 1.43, p = 0.005).

Conclusions: Let's learn about emotions is showing promising results and it is distinguishible from other universal interventions

by its manga figures and story-like approach. Future studies are warranted in order to investigate the effectiveness.

Childhood psychopathology dimensions as predictors of mood disorders among offspring at high risk of mood and substance use disorders

C. L. Vandeleur[1]*, S. Ranjbar[1], M.-P. F. Strippoli[1], E. Castelao[1], P. Marquet[1] and M. Preisig[1]

[1]Psychiatry, Lausanne University Hospital, Lausanne, Switzerland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.658

Introduction: Prospective longitudinal research on the offspring of parents with mood and substance use disorders allows to identify specific symptoms that occur before the onset of full-blown mood episodes in these offspring at high-risk of mood disorders.
Objectives: The goal of the present analysis was to assess early psychopathology dimensions measured by the Child Behavior Checklist (CBCL), completed by parents and separately by their offspring, as potential clinical manifestations occurring before the onset of mania/hypomania or major depressive disorder (MDD) in these offspring.
Methods: As part of a family study, we have collected information on 105 interviewed probands with bipolar disorder, 76 with MDD, 21 with substance use disorders (SUD) and 101 controls, as well as on their 239 children with follow-up information. The mean age of the offspring at study intake was 10.0 (s.d. 4.4) years and the mean follow-up duration was 16.3 (s.d: 5.6) years. The CBCL was completed by the parents describing their offspring as well as by the offspring themselves at their first assessment. Parent-offspring correlation coefficients were calculated and associations of the CBCL dimensions with the subsequent risk of mania/hypomania or MDD in offspring according to either informant were established using multinomial logistic regression models, adjusted for demographics, parental mood disorders or SUD and intrafamilial correlations.
Results: According to offspring reports, 17 of them developed mania/hypomania and 92 MDD over the follow-up. Offspring reported more withdrawn/depressed symptoms as predictors of mania/hypomania than controls, whereas parents reported their offspring to have more anxious/depressed symptoms before mania/hypomania. As predictors of MDD, offspring reported more withdrawn/depressed symptomatology but less somatic complaints than controls, whereas no significant predictors of MDD were identified by parents. Among the dyads where both offspring and parents had provided information (n=206), offspring were less likely to report rule-breaking behaviors as predictors of mania/hypomania, whereas their parents reported the opposite association. Parent-offspring correlations for all CBCL dimensions were statistically significant, ranging from 0.16 to 0.32, the correlation being 0.21 for rule-breaking behaviors.
Conclusions: Offspring and parental reports of predictors of mood disorders were discordant and the parent-child agreement for CBCL dimensions in the restricted sample was moderate. Whereas parent-offspring concordance for depressive symptoms as predictors of mania/hypomania in offspring was higher than for anxious or somatic problems, the reports of rule-breaking behaviors as predictors showed the highest discordance. This underscores the necessity to include information from multiple informants in the assessment of predictors of mood disorders in offspring.

A Computerized System for Identifying Preschool Children with Suspected Neurodevelopmental Disorders in Early Childhood Education

G. O. E. Muitana[1], L. S. Silva[1], V. F. Martins[1] and C. A. D. L. H. Amato[1]*

[1]Universidade Mackenzie, São Paulo, Brazil
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.659

Introduction: Early childhood is a critical phase where the foundations for many essential skills are established. It is also a crucial time to monitor children's development for early signs of neurodevelopmental disorders (NDD).
Objectives: This study aimed to develop a computerized system to help preschool teachers identify risk signs of NDD.
Methods: Phase 1: Development and validation of content and checklists - In the first stage, checklists were created to address four NDDs: ADHD, ID, ASD, and SLD. These were based on literature reviews and validated by four experts in neurodevelopmental disorders. The experts evaluated the checklists on two criteria: comprehensiveness and adequacy. Further assessment considered comprehension, objectivity, and precision of the checklist items, ensuring clarity for teachers using the system.
Phase 2: Development of the computerized system - The system was designed to assist early childhood educators in identifying children at risk for NDDs and supporting referral decisions, without diagnosing the disorders. Teachers begin by registering themselves and the child under observation. They then complete a checklist, indicating whether the child displays certain characteristics and the frequency of occurrence. A score of 1 indicates the presence of signs for ADHD, ID, ASD, or SLD, while 0 indicates absence. At the end of the process, the system generates a report with a risk level, which can be saved, edited, or printed for discussion with parents or specialists.
Results: Phase 1 - Content validation showed high scores, particularly for ASD and ADHD (1.00), while SLD scored lower (0.75). The overall Content Validity Index (CVI) for all disorders was 0.91. Experts suggested minor adjustments to the ADHD and SLD sections, especially concerning developmental characteristics that may vary by age. The checklists were further evaluated for reliability, yielding an overall CVI of 0.87.
Phase 2 - The computerized system was built using a RESTful API in Node.js, with the Nest.js framework. The frontend was developed as a Single Page Application (SPA) using Angular, and PostgreSQL was used for data storage. The system includes data validation through the Zod library and user authentication via JWT. It is designed to be a precise, low-cost screening tool for identifying, not diagnosing, NDDs. The system does not differentiate between severity levels or subtypes of disorders, reinforcing its role as a first-line identification tool.
Conclusions: Initial usability tests confirmed that the system is intuitive and suitable for its intended purpose. However, it is crucial to emphasize that the tool is not intended to operate autonomously.

It supports, but does not replace, comprehensive clinical evaluations and the expertise of qualified professionals in diagnosing NDDs.

Integrating impulsivity, emotional regulation, and latent behavioural profiles to predict adolescent mental health outcomes: A Comprehensive behavioural analysis

M. Grigoriou[1]*, J. von Trott[2,3] and P. Lalousis[2,3]

[1]Department of Psychology, University of Limassol, Limassol, Cyprus; [2]Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom and [3]Department of Psychiatry and Psychotherapy, Ludwig-Maximilian-University Munich, Munich, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.660

Introduction: Adolescence is a pivotal phase for behavioural development, where impulsivity, risk-taking, and emotional regulation mechanisms differentially impact mental health outcomes. This study examines the interaction of these factors in predicting addiction and behavioural disorders, focusing the identification of hidden behavioural profiles. The results seek to guide specific interventions for adolescents at risk.
Objectives: This study aims to: (1) investigate the predictive influence of impulsivity, risk-taking behaviours, and emotional regulation on addiction and mental health disorders in adolescents; (2) delineate distinct behavioural profiles using clustering analysis; and (3) recommend intervention strategies informed by these behavioural profiles and gender disparities.
Methods: Data were obtained from 853 adolescents aged 12 to 17 years from the NKI Rockland Sample, a continuous, institutionally focused initiative designed to establish a large-scale lifespan sample. Behavioural features were assessed via the UPPS-P Impulsive Behaviour Scale, the Emotional Regulation Questionnaire (ERQ), and the Youth Risk Behaviour Surveillance System. Clustering analysis, namely K-means and hierarchical methods, was employed to discern latent behavioural characteristics. Logistic regression and random forest models forecasted addiction and mental health outcomes, whereas time series analysis investigated emotional regulation trajectories across clusters.
Results: Clustering analysis revealed four distinct behavioural profiles: Cluster 1 (27%) exhibited few behavioural issues, Cluster 2 (15%) showed high levels of impulsivity and emotional dysregulation, Cluster 3 (38%) had moderate behavioural issues, and Cluster 4 (20%) had moderate-to-high behavioural and emotional difficulties. Emotional regulation trajectories indicated that cognitive reappraisal increased with age (mean score of 28 at ages 12-13 vs. 32 at 16-17), while expressive suppression decreased (mean score of 14 at ages 12-13 vs. 10 at 16-17) (Figure 1). Cognitive reappraisal was significantly associated with better behavioural outcomes, including lower hyperactivity ($r = -0.45$, $p < 0.01$) and aggression ($r = -0.38$, $p < 0.01$), particularly in females.

Image 1:

Conclusions: The interplay of impulsive traits, emotional regulation techniques, and risk behaviours is crucial in forecasting mental health consequences in teenagers. The recognition of unique behavioural profiles and gender-specific variations highlights the necessity for individualised interventions. Assessment of high-risk profiles, especially those characterised by elevated impulsivity and emotional dysregulation, along with the encouragement of cognitive reappraisal as a regulatory approach, can substantially reduce the likelihood of behavioural disorders and addiction.

Parental alcohol consumption during pregnancy and mental health of their children up to adulthood

Z. Mohrova[1]*, Z. Csajbók[2], L. Andryskova[3], A. Ksinan[3] and P. Brennan Kearns[1]

[1]Second Faculty of Medicine; [2]Faculty of Humanities, Charles University, Prague and [3]RECETOX, Faculty of Science, Masaryk University, Brno, Czech Republic
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.661

Introduction: Alcohol consumption of mothers can lead to problems in emotional and behavioural development of children. However, less is known about the effects of paternal alcohol drinking.
Objectives: We aimed to investigate whether maternal or paternal alcohol consumption during pregnancy longitudinally affected children's mental health.
Methods: We analyzed a total of 2,013 parent-child triads (52% of children were males) from the European Longitudinal Study of Pregnancy and Childhood. Data on alcohol consumption was obtained from questionnaires from both parents during pregnancy and after the child's birth. Mental health and behaviour of children was assessed with Strength and Difficulties Questionnaire (SDQ) at ages 7, 11, 15, and 18 years old, as reported by mothers and children themselves. The associations were tested using linear regression, adjusting for parent's age at child's birth, child's sex, and other socio-demographic and psychosocial covariates. We also tested an interaction between the exposure and children's sex.
Results: Maternal alcohol consumption was associated with higher total SDQ scores at ages 7, 11, and 18 years old when the outcomes were reported by mothers, but only at 11 when reported by children. We did not observe any dose-response relationship, and the effect size did not change during the follow-up. Results of the linear regressions are displayed in Table 1. We did not detect any effect modification by child's sex. The effects were observed across various domains of SDQ (except for the peer problems subscale): in the emotional symptoms subscale at age 11 when reported by both mother and child, in the conduct problems subscale at ages 7 and 11 when reported only by mother, in the hyperactivity/inattention subscale at age 18 when reported only by mother. Paternal alcohol consumption was not associated with the total SDQ score.

Table 1 Association of maternal alcohol consumption with the total score of Strength and Difficulties Questionnaire

		Maternal alcohol consumption during pregnancy	
	Child's age (years)	Once B (95% confidence interval)	Twice or thrice
SDQ reported by mothers	7	0.4 (-0.1, 0.9)	0.7 (0.1, 1.3)*
	11	0.7 (0.2, 1.2)*	0.6 (0.1, 1.2)*
	15	0.6 (0.0, 1.3)	0.5 (-0.2, 1.2)
	18	0.8 (0.0, 1.6)*	0.9 (0.1, 1.7)*
SDQ reported by children	11	0.1 (-0.4, 0.7)	0.8 (0.2, 1.5)*
	15	0.4 (-0.5, 1.2)	0.5 (-0.4, 1.4)
	18	0.1 (-1.4, 1.5)	-0.1 (-1.4, 1.2)

** p-value < .05. The reference category is no alcohol consumption. Results are from a fully adjusted model.*
Conclusions: Maternal alcohol consumption has a long-term effect on children's mental health in particular when reported by mothers. Interventions preventing maternal alcohol consumption during pregnancy may protect children's mental health.

Disclosure of Interest: None Declared

Hyperfocus in ADHD: A Misunderstood Cognitive Phenomenon

B. A. Oroian[1]*, P. Nechita[2] and A. Szalontay[1,2]
[1]"Grigore T. Popa" University of Medicine and Pharmacy Iasi and [2]" Socola" Institute of Psychiatry Iasi, Iasi, Romania
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.662

Introduction: Attention-Deficit/Hyperactivity Disorder (ADHD) is characterized by deficits in attention, impulsivity, and hyperactivity, but some cognitive phenomena within ADHD remain under-researched. One such phenomenon is hyperfocus, referring to prolonged, intense concentration on tasks of high interest. While inattentiveness is a hallmark of ADHD, hyperfocus presents a paradox where individuals become deeply absorbed in activities, often neglecting other necessary responsibilities. This focus can lead to productive work but also negative outcomes like missed deadlines or personal neglect.
Objectives: This study investigates the prevalence of hyperfocus in adults with ADHD, explores its relationship to core symptoms, and examines its impact on functional outcomes, including academic performance, employment, and relationships. It also seeks to understand individuals' perceptions of hyperfocus's benefits and drawbacks.
Methods: A mixed-methods approach was used to capture both quantitative and qualitative data. A total of 50 adults diagnosed with ADHD, aged between 18 and 45, were recruited. Participants completed the ADHD-Focused Attention Questionnaire (AFAQ), designed to measure the frequency, intensity, and duration of hyperfocus episodes. Additionally, the participants were asked to complete a structured life events questionnaire, assessing the impact of hyperfocus on various functional domains, including academic performance, employment, and personal relationships.
Results: The study found that 68% of participants reported frequent hyperfocus, with episodes lasting from several hours to days. The most common triggers were work-related tasks (35%), creative activities (25%) and gaming (20%),. While hyperfocus during gaming and creative tasks brought personal satisfaction, it often resulted in neglected responsibilities (40%). Hyperfocus at work increased productivity for 30% of participants, particularly in flexible or creative roles. There was also a strong correlation between hyperfocus and productivity, especially in flexible environments. However, hyperfocus also correlated with missed deadlines and neglected self-care, especially in less structured routines. Interviewees highlighted hyperfocus as a double-edged sword: it provided intense concentration but left many feeling "trapped," struggling to shift attention. Regarding relationships, 55% of participants said hyperfocus negatively impacted their social lives, with partners feeling neglected. However, 15% found that hyperfocus occasionally enhanced shared activities.
Conclusions: Hyperfocus in ADHD boosts productivity but can disrupt routines and relationships. Its unpredictability complicates balancing responsibilities. Recognizing hyperfocus as a core feature in ADHD could lead to better management strategies, such as time management training, external reminders, and structured breaks.

Attention-Deficit/Hyperactivity Disorder (ADHD) In Childhood, A Warning Sign Of Bipolar Disorder?

R. Tarazhi[1]*, V. Alikaj[1] and V. Skendi[1]

[1]Child and Adolescent Psychiatry, Psychiatric Hospital, Tirana, Albania
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.663

Introduction: Early-onset bipolar disorder (BD) and attention-deficit hyperactivity disorder (ADHD) have recently been the subject of a highly controversial debate, due to theories regarding the underlying pathophysiological processes and a clinical overlap of symptoms. Epidemiological data, clinical aspect, neuroimaging, neurochemical and genetic studies suggest that there may be a possible relationship between biological factors and clinical characteristics in the development of symptoms.
Objectives: Investigation of the prevalence of ADHD symptoms in bipolar patients compared to the control group.Investigating differences in age of onset, clinical presentation, and course of affective illness between bipolar disorder patients with childhood ADHD symptoms compared to those without childhood ADHD symptoms.
Methods: The study included 20 patients with bipolar disorder, hospitalized in the Psychiatric Hospital accompanied by their parents/relatives and 30 healthy controls (matched age, sex, socio-economic status) recruited through avalanche sampling in the Directorate of QSU "Mother Tereza". The Abbreviated International Neuropsychiatric Interview (MINI) was used to identify cases with bipolar disorder or possible psychiatric pathology. The Diagnostic Interview for ADHD Adults (DIVA 2.0) was used to explore the presence of symptoms of attention deficit hyperactivity disorder (ADHD) in childhood and at the current age.Descriptive analysis in SPSS was used for data analysis.
Results: It resulted that 80% of bipolar patients had ADHD symptoms in childhood compared to 16.67% in the control group. The age of onset of bipolar disorder was 17.31 years earlier in the group of cases with history of ADHD in childhood compared to the age of 21.25 years in cases without ADHD in childhood. In cases with history of ADHD, 43.75% had longer duration of manic episodes/hypomanic compared to 25% in the group of cases without childhood ADHD. The number of suicide attempts 1 or >1 was more frequent in patients with a history of ADHD (25% and 12.5 %) compared to cases without a history of ADHD (25 %). In psychotic symptoms during mania, it was found that in patients with a history of ADHD in childhood, the prevalence was higher (81.82%) compared to (50%) in those without a history of ADHD in childhood. The prevalence of adult ADHD in cases was 35% compared to controls 6.66%. Apparently, the number of cases with comorbid ADHD with impaired social/family functioning was higher compared with the group of controls with comorbid ADHD.
Conclusions: The associations of each clinical component of bipolar disorder with the presence or absence of ADHD in childhood were not statistically significant. However, it is worth noting that in complexity, the number of patients with more severe features of bipolar disorder is higher in cases with ADHD in childhood compared to cases without ADHD in childhood in our sample.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.664

Introduction: Depression is a prevalent yet frequently underdiagnosed condition in patients with dementia, exacerbating cognitive decline and emotional health. The combination of depressive symptoms with dementia-related cognitive deficits complicates accurate diagnosis and management of depression in this group of patients. Improved diagnostic instruments specifically designed for dementia patients are essential for improving detection and treatment outcomes.
Objectives: To evaluate the prevalence and diagnostic challenges of depression in dementia, focusing on symptom overlap. Additionally, it aims to assess the efficacy of diagnostic tools and management strategies to improve patient outcomes.
Methods: A systematic review of the literature was performed to evaluate the prevalence, symptomatology, and diagnostic difficulties of depression in dementia.
Results: The results reveal a substantial intersection between the cognitive and emotional symptoms of dementia and depression, encompassing apathy, anhedonia, and mood disorders. The coexistence of these symptoms frequently results in the underrecognition of depression or its misattribution to the dementia process. Instruments such as the CSDD and NPI showed higher sensitivity in identifying depression among dementia patients. Pharmacological therapies, including psychotherapy and individualized behavioral interventions, demonstrated improvements in mood and cognitive function; nevertheless, therapeutic success fluctuated according to the stage of dementia.
Conclusions: Depression in dementia patients has distinct diagnostic and treatment issues owing to symptom overlap and cognitive deterioration. Enhanced diagnostic instruments, including the CSDD, NPI, and GDS, provide superior distinction of depression symptoms from dementia-related deficits. Early recognition and tailored treatment strategies, integrating pharmaceutical and behavioral interventions, may alleviate depression symptoms and enhance overall patient outcomes. Interdisciplinary collaboration is crucial for enhancing care.

Adaptation and agreement analysis of an ADHD symptom observation instrument for adults with ASD in a specific residential setting

P. Ulsen[1], L. R. R. Carreiro[2]*, S. M. Blascovi-Assis[2] and M. A. Munoz[1]

[1]Universidad de Granada, Granada, Spain and [2]Universidade Presbiteriana Mackenzie, São Paulo, Brazil
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.665

Introduction: Attention Deficit Hyperactivity Disorder (ADHD) is a neurodevelopmental disorder characterized by attention problems, hyperactivity, and impulsivity that can persist into adulthood. Autism Spectrum Disorder (ASD) is also a neurodevelopmental disorder with deficits in communication and social interaction, as well as restricted interests and stereotyped behaviors. High comorbidity between ASD and ADHD suggests an overlap of the two disorders, which can exacerbate the severity of both conditions.
Objectives: Adapt and analyze the inter-rater reliability of a protocol for observing symptoms of ADHD and evaluate the presence of these symptoms in a sample of adults diagnosed with ASD.
Methods: The study was conducted at a residential center dedicated to the care of adults with ASD in Granada - Spain. The experimental procedure was approved by the Ethics Committee of the University of Granada. The adapted version of the protocol for observing symptoms of ADHD in adults with ASD, consisting of 19 items that evaluate three areas: inattention; hyperactivity, and impulsivity. The response options were: Never=1, Rarely=2, Sometimes=3, Often=4, Very Often=5. The questionnaire was translated into Spanish by experts. Items were adapted to better reflect the daily activities in the residential setting. Behavior of the participants was recorded by 2 observers, the Caregiver and Technical Staff (Psychologists or Occupational Therapists), who had known the participant for at least 6 months. Each professional received training on how to fill it out. Analyses consisted of a reliability test to evaluate the agreement and consistency of the observers' responses using the Intraclass Correlation Coefficient (ICC) through a two-factor Mixed Fixed-Effects Model. The presence of ADHD symptoms in the sample of 20 participants (14 men) diagnosed with ASD was tested descriptively.
Results: The results for agreement on ICC were: 9 items were below .5 (poor); 3 items between .5 and .75 (moderate); 7 items between .75 and .9 (good). For consistency, the results were: 7 items below .5; 5 items between .5 and .75; 7 items between .75. The ICC result for absolute agreement (ICC = 0.943; 95% CI = [0.900, 0.973]; $p < 0.001$) was .94, indicating reliability above 0.9 (excellent). The ICC result for consistency (ICC = 0.949; 95% CI = [0.911, 0.976]; $p < 0.001$) was .94, with reliability above 0.9. The mean scores for the presence of ADHD symptoms indicate that both Caregivers and Technicians most frequently rated the items as 2 (Rarely) and 3 (Sometimes).
Conclusions: In the overall instrument analysis, the results of interobserver agreement and response consistency reinforce that the adapted instrument is useful to identify ADHD behaviors in individuals with ASD. The need to continue developing and adapting instruments to identify comorbidities between profiles remains important.

Is the current UK guidance for treatment of co-occurring substance use and mental health problems being implemented in practice?

L. Goodwin[1]*, Z. Swithenbank[1], P. Irizar[2], K. Jackson[3], L. Halsall[1], J. Puddephatt[4], P. Parkes[5], C. Angus[6], A. Ushakova[1], J. Knight[1], F. Lobban[1], C. Drummond[7] and A. O'Donnell[3]

[1]Lancaster University, Lancaster; [2]University of Manchester, Manchester; [3]Newcastle University, Newcastle; [4]Edge Hill University, Ormskirk; [5]Expert Citizens, Stoke-on-Trent; [6]University of Sheffield, Sheffield and [7]King's College London, London, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.666

Introduction: Substance use and mental health problems commonly co-occur. Yet, people experiencing both problems commonly face barriers to getting the support they need and experience increased physical morbidity and premature mortality, compared to those with only one problem. In the UK, current guidance on treatment of co-occurring alcohol and mental health problems exist which set out standards for ways of working with this population, and how and where treatments should be offered.
Objectives: Through a secondary qualitative analysis and a systematic review, we aimed to determine the extent to which the UK guidance for care for people with co-occurring problems is being implemented.
Methods: A secondary qualitative analysis was conducted of interview transcripts from people with co-occurring depression and hazardous/harmful alcohol (N = 39). In addition, a systematic review was conducted to identify studies published in the UK since 2017 which focueds on treatment for adults with co-occurring substance use and mental health problems. For both data sources, a deductive coding framework was developed based upon the UK guidance and a thematic analysis was applied.
Results: The qualitative analysis identified four key themes from the service user perspective: Wrong doors and stigma; Responsibility and coordination of care; 'Don't discharge me' and Impacts of gaps between services. The review identified three main themes: Challenges to care for co-occurring conditions; Integration of care; and System and structural level barriers. Both studies showed that making initial contact with services was challenging, as was continued engagement with treatment. Staff attitudes and knowledge were important, because the therapeutic alliance had a significant impact on treatment outcomes and recovery. Stigma, both intrinsic and extrinsic, was identified as a barrier to accessing, engaging with, and delivering support. Both studies found evidence of inconsistent treatment offerings and conflicting advice or support, especially around the most appropriate way to treat co-occurring conditions. Barriers and facilitators were evident across individual, organisational and systems levels. Findings indicate that people are often not receiving the care they need in the ways in which guidance recommends.
Conclusions: The results suggest that despite existence of current guidance in the UK, implementation is inconsistent. This work has identified specific areas for improvement around access to treatment and a need for better coordination and integration of care. It highlights the need to explore how guidance can be better embedded in current practice to improve experiences and outcomes for this population.

Charles Bonnet syndrome: predisposing factors and more effective pharmacology therapy

E. I. Koiliari[1,2,3]*, I. Mouzas[1,2] and E. L. Pasparakis[1,2]

[1]Department of Psychiatry, General Hospital of Agios Nikolaos of Lasithi, Agios Nikolaos of Lasithi; [2]Department of Pathology, Laboratory of Alcohology of the Medical School of the University of Crete and [3]Department of Pathology, University General Hospital of Irakleion (PAGNI), Herakleion, Greece
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.667

Introduction: Charles Bonnet syndrome (CBS) is a condition in which patients with a free psychiatric history manifest visual hallucinations on the basis of a diagnosed ophthalmic disease (brain disease or optic nerve damage), which causes severe vision loss (partial or total).
Objectives: Hypothesis testing: "Administration of low doses of typical and atypical antipsychotics is the more effective pharmacological treatment for visual hallucinations of CBS".
Methods: Patients underwent pathological, psychiatric and ophthalmological assessment, resulting in a complete study-appropriate medical history.
Results: The sample consisted of ten female patients and eight male patients. The median age of the sample was 84 years. None of the patients was diagnosed with major psychopathology and in no clinical case was an individual medical history of dependence on alcohol or other psychotropic substances recorded. A common cause of the dysfunctional vision of the entire sample of patients was the visual deficit due to a diagnosed cataract condition. During the examination of each patient, it was found that a significant number of predisposing factors for CBS, as described in the literature, were detected. Increased stress levels, depressed mood, cognitive deficits, damage at the level of brain tissue, living conditions of the patient in environments with insufficient light intensity, social withdrawal or poor interaction with others contributed to the vulnerability of visual hallucinations. The administration of broad-spectrum medicines of Internal Medicine was also recorded as a covariate for the triggering of visual hallucinations. As demonstrated by the majority of patients, the administration of a low dose of a typical antipsychotic led to effective treatment of the syndrome.
Conclusions: Based on the present study, in patients of both sexes (men and women), aged 73-98 years, haloperidol and risperidone in low doses of 1-2 mg and olanzapine in low doses of 2.5-5 mg appear to be more effective options in treating with optical hallucinations in CBS.

"Improvements in Reflective Functioning in Patients with Treatment-Resistant Depression and Personality Disorder Treated with Esketamine"

M. Olivola[1]*, F. Mazzoni[2], G. Alessandro[2], A. Silva[2], N. Brondino[3] and F. Calorio[4]

[1]Department of mental health, ASST FBF SACCO, Milano; [2]DEPARTMENT OF BRAIN AND BEHAVIOURAL SCIENCE, ASST PAVIA; [3]DEPARTMENT OF BRAIN AND BEHAVIOURAL SCIENCE, University of Pavia, PAVIA and [4]Department of mental health, ASST PAVIA, Voghera, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.668

Introduction: Reflective functioning, the cognitive ability to interpret both one's own and others' behaviors in terms of underlying mental states such as emotions, desires, intentions, and beliefs, is essential for effective social interaction, emotional regulation, and self-awareness and is compromised more in Personality disorders. In the context of depression, reflective functioning can be particularly compromised, leading to difficulties in processing emotional experiences and managing social interactions. (Williams, 2010; Luyten, 2013)
Objectives: This study aims to understand the impact of esketamine on RF.
Methods: Tool test: Montgomery-Åsberg Depression Rating Scale (MADRS) and the Reflective Functioning Questionnaire (RFQ-8), to monitor changes in depressive symptoms and mentalization ability across six stages of treatment with Spravato: before treatment (T0), after 1 week (T1), 1 month (T2), 2 months (T3), 3 months (T4), and 6 months (T5) of Spravato treatment.
Results: The analysis revealed significant positive correlations between mentalization scores and the severity of depressive symptoms (MADRS):

- **T1 Mentalization and T1 MADRS:** The Pearson correlation coefficient of 0.349 indicates a moderate positive relationship, suggesting that poorer mentalization at Time 1 (T1) is associated with more severe depressive symptoms at the same time point.
- **T0 Mentalization and T3 MADRS:** The Pearson correlation coefficient of 0.392 shows a moderate positive association between mentalization at Time 0 (T0) and depressive symptoms at Time 3 (T3), indicating that poorer mentalization at T0 is related to more severe depressive symptoms later.
- **T2 Mentalization and T3 MADRS:** A Pearson correlation coefficient of 0.384 indicates a moderate positive relationship between mentalization at Time 2 (T2) and depressive symptoms at Time 3 (T3), suggesting that lower mentalization at T2 correlates with higher depressive symptoms at T3.

Image 1:

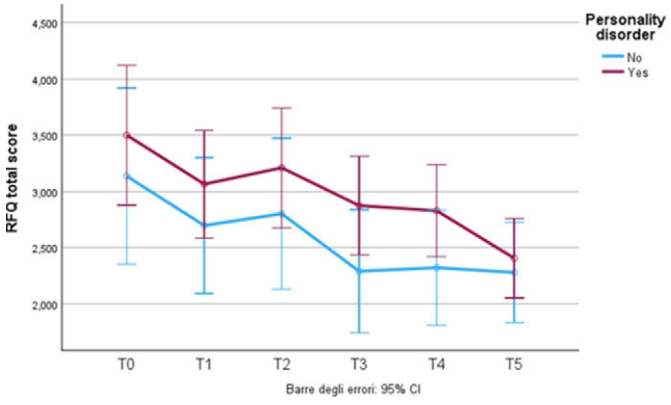

Image 2:

Category	Count	Percentage
Males	15	41.7%
Females	21	58.3%
Not Using SSRIs	16	44.4%
Using SSRIs	20	55.6%
Not Using SNRIs	24	66.7%
Using SNRIs	12	33.3%
Not on Other Antidepressants	24	66.7%
On Other Antidepressants	12	33.3%
Not on Antipsychotics	13	36.1%
On Brexpiprazole	6	16.7%
On Aripiprazole	7	19.4%
On Olanzapine	3	8.3%
On Quetiapine	6	16.7%
On Amisulpride	1	2.8%
Using Mood Stabilizers	15	41.7%
Not Using Mood Stabilizers	21	58.3%
Using Non-Pharmacological Therapies	16	44.4%
Not Using Non-Pharmacological Therapies	20	55.6%
With Personality Disorder	21	58.3%
Without Personality Disorder	15	41.7%

Conclusions: The study assessed the effects of esketamine on depressive symptoms and reflective functioning (RF) in patients with treatment-resistant depression (TRD) and a 58% comorbidity rate of personality disorders. These findings underscore the potential impact of mentalization on the severity and trajectory of depressive symptoms. The observed correlations indicate that patients with mentalization scores above 3.5 generally report higher levels of depressive symptoms. These results highlight the significant role of mentalization in influencing the severity and progression of depressive symptoms.

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.669

Introduction: People with schizophrenia have a higher prevalence of type 2 diabetes than the background population due to adverse effects from antipsychotics, lifestyle, and genetics.
Objectives: This study aims to explore the illness and treatment burden, mental well-being, and received support for illness management among people with schizophrenia and type 2 diabetes.
Methods: 62 Danish adults recruited from psychiatric outpatient clinics participated in this cross-sectional study using a survey developed for this specific purpose. The survey included measures of burden of illness and treatment (daily impact of diabetes and schizophrenia, multimorbidity treatment burden, diabetes empowerment), mental well-being (general well-being and diabetes distress), and social relations and support (general and illness-specific support). Descriptive analyses of survey data were conducted.
Results: Participants reported very negative daily impact from living with schizophrenia. However, diabetes also negatively impacted physical health, emotional well-being, and feelings about their future. 55% reported high treatment burden, 74% reported low/moderate diabetes empowerment. Approximately 30% had high levels of diabetes distress and 49% reported low general well-being. Half of the participants reported needing support for managing type 2 diabetes equal to schizophrenia.
Conclusions: Living with schizophrenia and type 2 diabetes often involves high burden of illness and treatment, low diabetes empowerment, high levels of diabetes distress and low general well-being. This study highlights a need for engaging mental health professionals, care coordinators, family and friends in daily diabetes management in future interventional studies and clinical practice.

Negative and depressive symptomatology in dual psychosis: three-month follow-up comparative analysis

C. Rusen[1,2*], R. Gimeno[1,2], J. Renau[1,2], M. Cabañes[1], A. Moreno[1] and M. Peraire[1,2]

[1]Department of Mental Health, Consorcio Hospitalario Provincial Castellon and [2]Universidad Cardenal Herrera-CEU Universities, TXP Research Group, Castellon, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.670

Introduction: Within the range of psychotic symptoms, negative symptomatology is the one that presents the least effective treatments. Depressive symptoms share characteristics with this symptomatology, making it difficult to distinguish between the two (Edwards *et al.* Psychol.Med. 2019; 1-13). In daily practice, antidepressants are used to treat the negative symptoms of psychosis, due to the absence of therapeutic alternatives.

Objectives: The aim of this work is to analyse the correlation between these symptomatic groups, comparing the effectiveness of treatment with antidepressants during a three-month follow-up.
Methods: Longitudinal and prospective clinical trial on a sample of 127 patients (95 men, 32 women) with dual psychosis (85 with schizophrenia, 42 with schizoaffective disorder), recruited from community or hospital facilities of the Hospital Provincial of Castellon. The mean age was 38.5 years. Antidepressant prescription was analysed at 4 different times, each month during follow-up, with PANSS-N for negative symptoms and MADRS and CDSS for depressive symptomatology.
Psychometric comparisons were made between the intervention group (16 patients with prescribed antidepressants, in therapeutic doses during the three months) and the control group (111 patients).
Results: Regarding the correlation between the 3 scales, we observed that at T0 there is no significant correlation, while at T1, T2 and T3 this correlation is significant ($p<0.01$), as the scores improve. A progressive increase in Pearson's coefficient (PCC) is observed between T1 and T3, emphasizing a higher correlation between MADRS and CDSS (PCC of 0.920 at T3) with respect to PANSS-N and the other two questionnaires (PCC of 0.587 and 0.619 at T3, respectively).
Comparing the means between the scales, there is a significant decrease in MADRS between T0 and T3 (61.8% decrease from baseline, F: 4.49, $p<0.05$), as well as in CDSS (-68.7%, F: 4.53, $p<0.05$). In PANSS-N there are no significant differences (F: 0.57, p: 0.45), despite a relative decrease of 51.9%.
Considering clozapine prescription, there is a significant decrease in MADRS and CDSS during the first month, with no differences in PANSS-N throughout the evolution.
Conclusions: The reduction obtained in the MADRS and CDSS scales can be associated with the prescription of antidepressants, as opposite to the reduction obtained in PANSS-N. This implies that antidepressants do not influence the reduction in negative symptoms, reflecting the clinical impression that the two entities are distinct (despite areas of overlap).
The analysis using clozapine treatment reinforces the existence of a different idiosyncrasy between symptomatic groups. This can be explained at the neurobiological level by the different mechanisms of action involved (monoamine depletion vs. dopaminergic blockade), but keeps the debate open as to how they can be differentiated and treated in clinical practice.

Evaluating the Prevalence and predictors of anxiety and depression among elementary and high school educators in Canada.

A. Belinda[1]*, Y. O. Wei[1], R. D. L. D. Dias[2], A. Orimalade[1], P. Brett-MacLean[1] and V. I. O. Agyapong[1,2]

[1]University of Alberta, Edmonton and [2]Dalhousie University, Halifax, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.671

Introduction: Globally, anxiety and depression are primary contributors to work disability and are associated with the mental and physical well-being of educators.Anxiety and depressive disorders result in poor mental health, great human misery, enormous loss in economic output and increased public health and economic burden.
Objectives: To determine the prevalence and independent predictors of likely Generalized Anxiety Disorder (GAD) and likely Major Depressive Disorder (MDD) among teachers in Newfoundland and Labrador, Alberta, and Nova Scotia.
Methods: The study utilized a cross-sectional design. Educators in the three Canadian provinces completed an online survey after enrolling on the Wellness4Teachers program, a daily supportive text messaging program. Likely GAD and likely MDD among subscribers were respectively assessed using the Generalized Anxiety Disorder-7 scale and Patient Health Questionnaire-9. Data was analyzed with SPSS version 28.
Results: Overall,763 out of the 1912 subscribers of the Wellness4Teachers program completed the survey, resulting in a 39.91% response rate. The prevalence of likely MDD was 55.7%, and likely GAD was 46.0%. Participants who experience high stress were 7.24 times more likely to experience MDD (OR = 7.24; 95% CI: 4.22–12.42) and 7.40 times more likely to experience GAD (OR = 7.40; 95% CI: 4.63–11.80) than those with mild to moderate stress. Again, participants with emotional exhaustion were 4.92 times more likely to experience MDD (OR = 4.92; 95% CI: 3.01–8.05) and 4.34 times more likely to experience GAD (OR = 4.34; 95% CI: 2.47–7.62) than those who did not. Similarly, respondents with low resilience were 3.01 times more likely to experience likely GAD compared to those with normal to high resilience (OR =3.01; 95% CI: 2.03-7.62). Sociodemographic and work-related variables did not independently predict the presence of likely GAD and likely MDD.
Conclusions: The current study reinforces the need for governments and policymakers in the education sector to implement appropriate and comprehensive mental health support programs to address the unique stressors faced by educators, reduce emotional exhaustion and improve resilience as a way to reduce anxiety and depression, promote their well-being and enhance the quality of educational delivery.

Multimodal MRI Analysis of Brain Metrics Associated with Depression Remission

G. Clain[1], M. Malestroit[1], J. Deverdun[2], E. Le Bars[2], V. Brand-Arpon[1], P. Courtet[1,3], D. Ducasse[1] and E. Olie[1,3]*

[1]Emergency Psychiatry and Acute Care, Lapeyronie Hospital, CHU Montpellier; [2]Departement of Neuroradiology, Institut d'Imagerie Fonctionnelle Humaine I2FH platform, Gui de Chauliac, CHU Montpellier and [3]CNRS, INSERM, IGF, Montpellier University, Montpellier, France
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.672

Introduction: Treatment-resistant depression is particularly challenging in individuals with a history of suicide, often associated with lower rates of remission. The antidepressant efficacy of Acceptance and Commitment Therapy (ACT) in individuals with a history of suicide has been demonstrated (Zhao B, et al. Ann Gen Psychiatry 2023;22:34). It is crucial to further understand the underlying mechanisms driving this therapeutic effect.

Objectives: To investigate cerebral biomarkers of therapeutic response to Acceptance and Commitment Therapy (ACT) versus Progressive Relaxation Therapy (PRT) in depression and suicidal risk.
Methods: This randomized controlled trial included 32 patients with a history of suicide attempts in the past year who underwent seven weekly sessions of ACT or PRT. They completed clinical and MRI examinations (resting state, diffusion tensor, cerebral blood flow measured by pCASL, and anatomical sessions) at baseline and after therapy completion. Resting-state functional changes (graph theory, functional connectivity) in two networks identified in previous depression studies (Zhang X, Xu R, Ma H, et al. Biol Psychiatry 2024;95:1091-1099), according to the Schaefer atlas, were measured between groups and in the entire sample. A Principal Component Analysis (PCA) was conducted to combine depression, hopelessness, and psychological pain into a single composite variable, explaining 77.8% of the variance with strong correlations to the original variables: r = .91. This Depression Component (DC) was used in further analyses.
Results: The patients were predominantly women (87.5%) with a mean age of 40 years (SD = 12). 81% of patients experienced current depression. No significant Group x Time interaction was found. In the whole sample, no anatomy nor diffusion tensor metrics modification has been found. However, the reduction of the DC was negatively correlated with modularity (r = -0.476, pFDR < 0.05) for the Salience Ventral Attentional. Moreover, within this network the DC variable was negatively correlated with the cerebral blood flow of one region (r = -0.5, pFDR < 0.05) and positively correlated with functional connectivity (T = 4.72, pFDR < 0.05) (Figure 1).
Image 1:

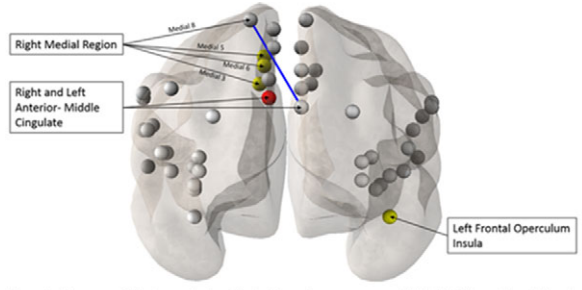

Figure 1 : Summary of Metrics correlating with the depression component variable in the Salience-Ventral-Attentional network. Red is for ROI with a CBF evolution significantly correlated to the depression component (pFDR < 0.05). Yellow represents ROI with a CBF evolution correlated to the depression component, with the correlation approaching significance (pFDR < 0.1). Blue line stands for functional connectivity evolution significantly correlated to the depression component (pFDR < 0.05). Medial 3 corresponds to part of the right middle cingulate cortex; Medial 5 corresponds to part of the precuneus; Medial 6 includes a portion of the paracentral lobule; Medial 8 encompasses part of the supplementary motor area and a small portion of the superior frontal gyrus.

Conclusions: These results suggest that the therapeutic response, and consequently the reduction of the depression component, might be related to a reorganization within the salience network. Modularity refers to how well a brain network is organized into distinct groups or clusters, where connections within each group are stronger than those between different groups. We observed increased modularity and cerebral blood flow within the salience ventral attentional network, which could reflect a more specialized and segregated functional organization. This reorganization could enhance the brain's ability to regulate emotional and cognitive processes, supporting recovery from depression.

Treatment Resistant Depression Rates and Related Clinical Variables in a Outpatient Clinic: Pilot data from Türkiye

S. Karabulut[1]* and M. Düzgün[1]

[1]Psychiatry, Akdeniz University School of Medicine, Antalya, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.673

Introduction: Major depressive disorder is a global mental health challenge imposing a serious burden on individuals and society. Treatment resistant depression (TRD) is most commonly defined as inadequate treatment response following at least two consecutive antidepressant trials of adequate dose, duration and treatment adherence. TRD is associated with high personal suffering, considerable functional impairment and significant mental health costs.
Objectives: This study investigated the rate of TRD in treatment-seeking outpatients with major depressive disorder and clinically-related variables. We hypothesized that patients with TRD would have more severe symptoms, chronic course and more hospitalization than patients without TRD.
Methods: The files of patients diagnosed with Major Depressive Disorder who had applied to the Outpatient Psychiatry within the last 3 months and had a follow-up history of at least 1 year were reviewed (n=204). Demographic and clinical data of the patients were recorded using a structured data form. Dutch Measure for quantification of Treatment Resistance in depression (DM-TRD) scores were calculated. The study was approved by the Akdeniz University Ethics Committee (approval date:22/8/2024).
Results: Regarding the index episode, the majority of patients had received selective-serotonin reuptake inhibitor (SSRI) treatment (22% escitalopram, 14.2% sertraline). 30.9% of the patients had received augmentation. After the first treatment trial, 21.1% of the patients had treatment-response, and 30.7% achieved remission. After the second treatment trial, 10.5% showed treatment-response, and 16.3% achieved remission. The proportion of patients meeting the criteria for TRD was 29.9%.
When comparing patients with TRD, the total number of depressive episodes was significantly lower (p=0.01), the duration from the onset of the index episode to treatment and recovery was longer (p<0.001, p=0.02; respectively) in those with TRD. The number of ECT episodes and rTMS sessions was higher (p<0.001, p=0.004; respectively), the DM-TRD score, the frequency of benzodiazepine use and the rate of inpatient treatment were also higher (p<0.001, p<0.001, p=0.01; respectively). The rate of non-adherence to treatment, the rate of chronic episodes and symptom severity were higher, functional impairment was more severe, and the frequency of comorbid personality disorders was higher (p<0.001, all).
Conclusions: To the best of our knowledge, this is the first study reporting TRD data from Türkiye. Our results showed that patients with TRD had more chronic and less repetitive illness course, duration of untreated depressive symptoms were longer, use of benzodiazepine, ECT and rTMS treatments were more frequent and longer than patients without TRD. These results should alert clinicians about subprofiles of patients with TRD to predict course and develop preventive effective strategies.

Modifiable Risk Factors for Perinatal Depression among Women with Family History of Psychiatric Disorders: a nationwide register-based study in Sweden

R. Keijser[1]* and D. Lu[1]

[1]Karolinska Institutet, Stockholm, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.674

Introduction: Perinatal depression (PND) is characterized by depressive episodes with an onset during pregnancy or following delivery. The clinical management of PND is however challenging because patients are often concerned of the potential harm of pharmaceutical therapy on foetus via placenta or breastfeeding. Previous findings have shown that women with a family history of psychiatric disorders (FhPsy) are at high risk for PND. However, no precision prevention strategy has been developed for this high-risk population.
Objectives: To identify risk factors modifying the risk of perinatal depression (PND) among women with a family history of psychiatric disorders (FhPsy).
Methods: We conducted a cohort study of 2,195,838 pregnancies of which 1,236,980 births between 2001-2021 in Sweden. PND was defined as a depression diagnosed, or antidepressant prescribed during pregnancy or within a year postpartum. FhPsy was assessed as any psychiatric disorder diagnosed before pregnancy among biological parents/siblings. Modifiable risk factors, i.e., snuff use and smoking before and during pregnancy, and BMI in early pregnancy and at delivery, were identified from registers. Multivariable logistic regression was used to estimate the OR of PND in relation to FhPsy, modifiable risk factors, and interaction effects.
Results: In total, 94,597 (4.35%) women were diagnosed with PND at a mean age of 31.24 (SD = 5.30) years. Women with a FhPsy had 2.6 higher risk of PND (95% CI 2.58-2.61). All modifiable risk factors were also positive associated with PND (ORs ranged from 0.79 - 2.34). Interaction effects were observed between FhPsy and the modifiable factors (*P*-for-interaction <0.05). Specifically, women with FhPsy using snuff three months prior to pregnancy had 3.54 times higher odds of PND (95% CI 3.54-3.78), compared with women without such history who were non-snuff users. However, the OR was attenuated by 61% among those with FhPsy yet no use of snuff (OR 2.19, 95% CI 2.17-2.23). Similar trends were found for heavy-smoking-to-no-smoking either before or during early pregnancy and for obesity-to-normal-weight either during early pregnancy or at delivery among women with FhPsy, with an OR attenuation ranging from 11% to 58%.
Conclusions: While women with a FhPsy are at risk for PND, modifying risk factors, i.e., smoking or snuff cessation and maintaining a healthy weight, may help lower such odds. Our findings have important implications for informing prevention strategies targeting the high-risk population.

Depression Prevalence, Screening, and Treatment Rates in Adolescents with Obesity in Ambulatory Settings

L. Li

Psychiatry, University of Alabama at Birmingham, Birmingham, United States
doi: 10.1192/j.eurpsy.2025.675

Introduction: Obesity is a growing problem in several developed countries and has a complex etiology in teenagers. Approximately one-third of children and adolescents in the United States are overweight or obese. However, it is not clear how depression and obesity are screened and treated in the primary care setting for adolescents.
Objectives: This study aims to describe the prevalence, screening, and treatment rates for depression in adolescents in ambulatory settings in the United States.
Methods: Data on 444,080,295 male and female adolescents ages 13-18 were extracted from the 2008-2018 CDC National Ambulatory Medical Care Survey datasets. Adolescents were stratified by weight groups based on CDC guidelines (i.e., body mass index percentile).
Results: Of the adolescents, 16.89% were obese, 13.81% were overweight, 43.39% were normal weight, and 25.91% were underweight. Depression screening rates in adolescents with obesity is 2.89%, overweight is 3.35%, normal weight 3.49%, and underweight is 2.83% (p=0.382). Prevalence of depression in adolescents with obesity is 7.17%, overweight is 6.04%, normal weight is 6.31%, and underweight is 12.14% (p<0.0001). Prevalence of counseling and psychotherapy in adolescents with obese status is 2.70%, overweight status is 2.89%, normal weight is 2.92%, and underweight is 11.27% (p<0.0001). Patients seen by primary care health workers, age, female gender, number of chronic conditions, and increased visits are significant predictors of depression diagnosis in adolescents.
Conclusions: Depression in adolescents who are overweight or obese is under-screened for, under-identified, and under-treated. More mental health counseling and psychotherapy must be offered to those with both depression and obesity.

EPP399

Sports therapy interventions and symptom severity in unipolar depression: an intervention study

C. A. Penkov[1]*, M. Wendt[1], K. Friedrich[1], C. Linke[1], L. Duda[1] and M. Ziegenbein[1]

[1]Klinikum Wahrendorff, 31319, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.676

Introduction: Physical activity can be therapeutically effective in the treatment of depressive disorders. There is a need for research in clinical practice both with regard to the framework conditions required for physical activity and whether the implementation of sports therapy under the conditions of everyday care can have an effect on physical fitness and depressive symptoms. This study

therefore examines the effect of sports and exercise therapy in the day-care treatment of unipolar depression.

Objectives:

- treatment of depressive disorders
- implementation of sports therapy under the conditions of everyday care

Methods: Patients with a depressive disorder as their main clinical diagnosis (F32./F33.) who underwent day clinic treatment for 5-11 weeks were included. People in the intervention and control groups completed a minimum of 2.0 and a maximum of 0.5 exercise sessions per week respectively. To investigate the effect of sports and exercise therapy on aerobic performance, the intervention group completed a submaximal, bicycle ergometric step test (PWC test), whereby the heart rate was measured over the individual exercise levels in a pre-post comparison. Furthermore, the change in depression symptoms between the intervention and control group was recorded at admission and discharge from treatment using the BDI-II.

Results: Patients in the intervention group (IG) showed a significantly greater reduction in depression symptoms compared to the control group (CG) (ΔBDI-II; M = - 8, p <.01).

In the pre-post comparison of PWC, IG achieved a significant increase in performance of 7 and 12 watts respectively (p <.05; t-test). Further inferential statistical results are reported.

Conclusions: Regular physical training can lead to a significant improvement in endurance performance and an improvement in depressive symptoms.

Examining the Relationship Between Depression, Rumination, and Anxiety: Insights from the DiSCoVeR Trial

L. Rubene[1,2*], L. Konosonoka[1], A. Sturmane[1], E. Dechantsreiter[3], F. Padberg[3], D. Bavelier[4], F. Hummel[5], T. Cohen[6], N. Lerner[6], O. Bonne[7], Y. Benjamini[8], A. Lotan[9], M. Nahum[6] and E. Rancans[1,2]

[1]Department of Psychiatry and Narcology, Riga Stradiņš University; [2]Riga Centre of Psychiatry and Addiction Disorders, Riga, Latvia; [3]Department of Psychiatry and Psychotherapy, LMU University Hospital, Munich, Germany; [4]Campus Biotech & Faculty of Psychology and Educational Sciences, University of Geneva; [5]Neuro-X Institute (INX) and Brain Mind Institute (BMI), École Polytechnique Fédérale de Lausanne (EPFL), Geneva, Switzerland; [6]School of Occupational Therapy, Faculty of Medicine; [7]Department of Psychiatry, Hadassah Medical Center, Faculty of Medicine; [8]Department of Statistics and Data Science, The Hebrew University of Jerusalem and [9]Department of Adult Psychiatry and the Biological Psychiatry Lab, Hadassah University Medical Center, Jerusalem, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.677

Introduction: The DiSCoVeR trial (The DiSCoVeR Project: Examining the synergistic effects of a cognitive control videogame and a self-administered non-invasive brain stimulation on alleviating depression) is a double-blind, sham controlled, randomized controlled trial (RCT) investigating the feasibility and efficacy of an innovative, self-applied treatment approach for patients diagnosed with major depressive disorder (MDD). The multi-site trial is conducted at three clinical trial sites (Hadassah, Israel; Riga Stradiņš University, Latvia; Ludwig-Maximilian-University, Germany). During the first study visit of this trial data on different patient baseline parameters were gathered including assesment of depressive symptoms, anxiety symptoms and rumination.

Objectives: The aim of this abstract is to examine the relationship between depression, rumination and anxiety in this patient sample. Rumination, often characterized by repetitive, negative thinking, can exacerbate symptoms of anxiety and depression by maintaining and intensifying negative emotional states. This cycle creates a challenging clinical problem making it difficult to break free without targeted interventions.

Methods: This analysis includes baseline data from 106 MDD patients enrolled in the DiSCoVeR trial as of April 2024. Depression severity was assessed using the Montgomery–Åsberg Depression Rating Scale (MADRS), anxiety symptoms were measured using the Generalized Anxiety Disorder Questionnaire (GAD-7), and rumination was evaluated with the Ruminative Response Scale (RRS). Data were analyzed using the Jamovi statistical platform, applying linear regression model to explore the relationship between depression, rumination, and anxiety. All assumptions for linear regression were met prior to analysis.

Results: The mean age of the participants in this study sample ranged from 18 to 63 years old (mean age 33.4 years). 65.7% of the participants were female. Regression analysis revealed a significant positive association between anxiety (GAD-7) and rumination (RRS), suggesting that increased anxiety symptoms are associated with higher levels of rumination (p < .001). However, age and gender were not significant predictors of rumination. While depression (MADRS) was moderately associated with rumination, this effect was not statistically significant. Educational level showed a marginal effect, with university-educated individuals showing higher rumination levels compared to those with professional education.

Conclusions: In this patient sample overall, anxiety (GAD-7 score) was the strongest predictor of rumination, while other factors such as depression, age, and gender did not show significant effects. Education level might have a marginal impact, especially for individuals with university education.

Impact of history of esketamine treatment in the current depressive episode on response to iTBS

M. Tonkul[1*], B. T. Baune[1] and E. Kavakbasi[1]

[1]Department of Psychiatry, University Hospital Münster, Münster, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.678

Introduction: An increasing number of patients with treatment-resistant depression (TRD) are treated with a novel form of transcranial magnetic stimulation (TMS): the intermittent theta burst stimulation (iTBS). In this retrospective naturalistic study, we analyzed the outcome of iTBS treatment in patients with treatment-resistant depression.

Objectives: To investigate the impact of history of esketamine treatment in the current depressive episode on response to iTBS.

Methods: In this study, we included 66 hospitalized patients (57.6% female; mean age, 52.7 years) from the University Department of Psychiatry, University of Münster. Prior to iTBS treatment, 10 patients were treated with esketamine (60% female; average age, 49.8 years) and 56 were not (57% female; average age, 53.25 years). A Chi-squared test was utilized to investigate the impact of history of esketamine treatment on response to iTBS.
Results: The overall response rate was 51.5%. Prior to iTBS, 15% of the patients were treated with esketamine in the current episode. In the patient group with history of esketamine treatment (ESK+), 40% of the patients responded to iTBS. In the patients without history of esketamine treatment (ESK-) in the current episode, the response rate to iTBS was 53.6 %. However, history of esketamine treatment in the current episode had no significant impact on iTBS outcome ($P = 0.505$; $\chi 2 = 0{,}626$; $df = 1$). The difference in baseline disease severity between the groups was not statistically significant (CGI-S 6.3 (ESK+) vs 6.1 (ESK-), $P = 0.281$; $F = 1.184$; $df = 64$). The total rate of treatment dropouts was 3%.
Conclusions: History of esketamine treatment in the current episode was associated with worse outcome of iTBS. This finding was not statistically significant. iTBS may be an effective (40% response rate) and safe treatment for patients who did not respond to esketamine therapy.

Self-Assessment Scales for Depression Screening: A Review of Recent Trends

A. Argyriadis[1]*, E. Kotrotsiou[1], S. Kotrotsiou[2], D. Katsarou[3], A. Patelarou[4], E. Patelarou[4], M. Efstratopoulou[5] and A. Argyriadi[5]

[1]Nursing, Frederick University, Nicosia, Cyprus; [2]Nursing, University of Patras, Patra; [3]Department of Preschool Education Sciences and Educational Design, University of the Aegean, Rhodes; [4]Nursing, Hellenic Mediterranean University, Heraklion, Greece and [5]United Arab Emirates University, Al Ain, United Arab Emirates
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.679

Introduction: Depression significantly impacts quality of life, and the growing global mental health burden necessitates effective strategies for early detection. Traditional diagnostic methods often involve clinician-led interviews and assessments, which can be time-consuming and may not always be accessible to individuals in underserved or remote areas. As a result, self-assessment scales have emerged as a valuable tool for initial depression screening, offering a cost-effective and timely alternative that empowers individuals to monitor their mental health independently.
Recent trends in self-assessment tools for depression highlight the development of digital platforms, such as smartphone apps and web-based applications, which allow for greater reach and real-time data collection.
Objectives: The primary objective of this study is to systematically review recent trends in the development and use of self-assessment scales for depression screening. With the growing global prevalence of depression and the necessity for early detection, self-assessment tools have become a widely adopted method for screening, offering the advantage of accessibility, cost-effectiveness, and user autonomy. This study aims to evaluate these tools in terms of their psychometric properties, including reliability, validity, and sensitivity, which are crucial for ensuring accurate and dependable depression detection.
Methods: A systematic review methodology was employed, focusing on studies published between 2015 and 2024. The sample included 40 peer-reviewed articles sourced from academic databases, with studies chosen based on their relevance to self-assessment depression screening tools. The sampling strategy involved selecting scales used in diverse settings, including clinical environments, schools, and online platforms. Key tools such as the Patient Health Questionnaire (PHQ-9), Beck Depression Inventory (BDI), and the Depression Anxiety Stress Scales (DASS-21) were analyzed.
Results: Results indicated an increase in the utilization of digital and app-based self-assessment tools, with advancements in adaptive testing and machine learning-based algorithms improving the accuracy and sensitivity of depression screening. Additionally, the results showed promising psychometric reliability and validity across different cultural contexts. However, the study also highlights challenges, including the potential for over-reliance on self-reporting and the underrepresentation of marginalized populations in the development of these tools.
Conclusions: Despite the significant advancements in self-assessment scales for depression screening, challenges remain in ensuring that these tools are both equitable and inclusive. One critical area for future research involves addressing cultural and demographic biases that may limit the effectiveness of these scales in diverse populations.

Examining the needs, outcomes, and current treatment pathways of 2461 people with Treatment-Resistant Depression: A mixed-methods study

K. Gill[1,2]*, D. Hett[2], M. Carlish[1], R. Amos[1,2], A. Khatibi[1], I. Morales-Munoz[1] and S. Marwaha[1,2]

[1]School of Psychology, Institute for Mental Health and [2]Birmingham and Solihull Mental Health NHS Foundation Trust, National Centre for Mental Health, Birmingham, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.680

Introduction: Major Depressive Disorder (MDD) is a pervasive global health issue, contributing significantly to disability and impaired quality of life. A substantial proportion of individuals with MDD develop Treatment-Resistant Depression (TRD), characterised by the failure to respond to at least two adequate antidepressant treatments (at an adequate dose and duration). TRD poses additional challenges due to its complex clinical presentation and limited treatment options, making it crucial to better understand its impact and develop more effective care strategies.
Objectives: To investigate the prevalence and clinical profiles of TRD in a large NHS Mental Health Trust and explore the treatment experiences and perceptions of TRD patients and healthcare professionals (HCPs) involved in their care.

Methods: A concurrent mixed-methods approach, incorporating patient and public involvement (PPIE), was used. Quantitative analysis of anonymised electronic health records (EHRs) identified the TRD cohort and key characteristics (e.g. age, gender, employment status). Binary logistic regression explored predictors such as comorbidities and service use. The qualitative component included semi-structured interviews with TRD patients (n=7) and HCPs (n=8), analysed using thematic analysis to explore lived experiences and treatment barriers. Findings from both approaches were integrated to provide a comprehensive understanding of TRD.
Results: TRD was prevalent in 48% of patients diagnosed with MDD. Predictors of TRD included recurrent depression (OR=1.24, CI 95%=1.05–1.45), comorbid anxiety (OR=1.21, CI 95%=1.03–1.41), personality disorders (OR=1.35, CI 95%=1.10–1.65), and cardiovascular diseases (OR=1.46, CI 95%=1.02–2.07). Qualitative findings highlighted the severe emotional impact of TRD on patients' lives and revealed significant dissatisfaction with treatment options, particularly frustration with the "trial and error" approach of pharmacological treatments. HCPs echoed concerns about the lack of standardised treatment pathways, with both groups emphasising the need for more holistic and personalised care, citing limited access as a serious barrier to effective treatment.
Conclusions: This study highlights the significant burden of TRD, affecting nearly half of MDD patients within the examined NHS Trust. By combining quantitative and qualitative methods, it offers a comprehensive understanding of TRD's prevalence and complexities. The findings support a shift toward holistic, patient-centred care, addressing institutional barriers and enhancing healthcare provider resources to improve outcomes.

Changes in depression medication following the initial assessment by specialised psychiatry services in the Helsinki-Uusimaa Region

J. Juntura[1]*, P. Näätänen[2], G. Joffe[2], J. Ekelund[2], R.-L. Leskelä[3], T. Ito[4], B. Rive[5], Y. Godinov[6], I. Eriksson[7] and P. Torkki[1]
[1]University of Helsinki; [2]Department of Psychiatry, Helsinki University Hospital, Helsinki; [3]Nordic Healthcare Group, Espoo, Finland; [4]Janssen EMEA, High Wycombe, United Kingdom; [5]Janssen EMEA, Paris, France; [6]Janssen EMEA, Sofia, Bulgaria and [7]Janssen EMEA, Solna, Sweden
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.681

Introduction: Depressive disorders often require specialised psychiatric services. Timely, appropriate medication initiation and/or change plays a crucial role in improving patient (pt) outcomes (Kraus *et al.* Transl Psychiatry 2019;9 127).
Objectives: Describe the type of, and time to, medication changes within 12 months of the initial assessment of pts with depression recorded by specialised psychiatric care (SPC).
Methods: This cohort study leveraged Finnish pt data from 19 registries from 2014– 2020. Adult pts with a depression diagnosis recorded by SPC in the Helsinki and Uusimaa region in 2015 (with no depression diagnosis given by SPC within the previous year) were included. All treatments were recorded as monotherapy or combination/augmentation therapy. The Kaplan-Meier method was used to analyse time to treatment change (TTC).
Results: 9305 pts were included; baseline characteristics are reported (**Table 1**). There was no change to the baseline treatment status in 39.7% of pts (**Table 2**). The most common change was from no medication to monotherapy (2138 pts [45.6% of those with no treatment before]). 2202 (23.7%) pts remained untreated throughout the study. Median (95% confidence interval) TTC following the initial assessment by SPC was 53 (50–56) days (**Figure 1**).
Image 1:

Table 1. Baseline characteristics

	Total (N=9305)
Age, years, mean (standard deviation)	43.7 (14.6)
Gender, male, n (%)	3420 (36.8)
Medications before first SPC assessment, n (%)	
0	3581 (38.5)
1	3984 (42.8)
2	1452 (15.6)
3+	288 (3.1)

Medications before first SPC assessment were used for ≥4 weeks in the 12 months prior.
SPC: specialised psychiatric care.

Image 2:

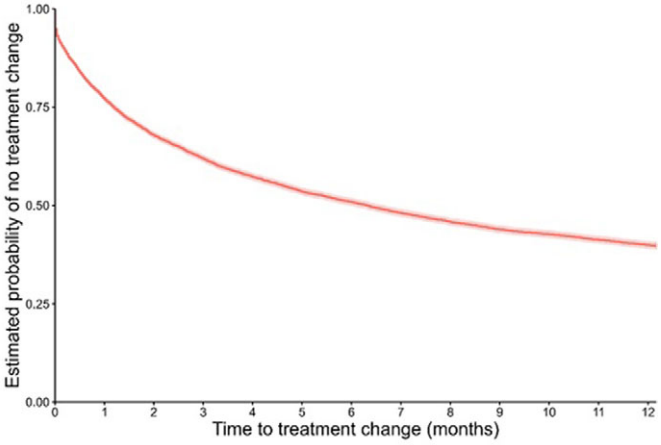

Table 2. Medication changes[a] following first SPC assessment, n, (%, calculated per 'treatment before' category)

From\To	No ongoing medication[b]	Monotherapy	C/A therapy[d]	No change
No ongoing medication[b]		2138 (45.6)	348 (7.4)	2202 (47.0)
Monotherapy	1417 (37.3)	261 (6.9)[c]	810 (21.3)	1312 (34.5)
C/A therapy[d]	75 (9.2)	414 (50.7)	150 (18.4)[c]	178 (21.8)

Treatment before/after: the latest ongoing treatment ≤12 months before consultation/the first treatment initiated ≤12 months since consultation.
[a]Medications were categorised as selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, TCAs, monoamine oxidase inhibitors, mood stabilisers, atypical antipsychotics or "other antidepressants"; [b]For 30 days prior to first SPC assessment; [c]Substance class changes: changes within therapy type; [d]Combination: use of ≥2 medications simultaneously for ≥30 days; Augmentation: addition of atypical antipsychotics, quetiapine, lithium or lamotrigine to existing antidepressant therapy for ≥30 days. C/A: combination/augmentation; SPC: specialised psychiatric care; TCA: tricyclic antidepressants.

Image 3:

Figure 1. Time to treatment change

Treatment change reported as a composite of all possible changes. For the full population (N=9305), median (95% CI) TTC was 189 (178–200) days. For pts experiencing treatment change within 365 days after consultation (N=5613), TTC was 53 (50–56) days.
CI: confidence interval; TTC: time to treatment change.

Conclusions: Around 40% of pts referred to SPC had no prior pharmacotherapy. Monotherapy was the most common treatment provided. Almost 40% of pts had no change in their baseline treatment over 12 months, highlighting the need for further research to optimise care.

Disclosure of Interest: None Declared

Real world clinical practice, efficacy and safety of esketamine nasal spray in MDD patients: the French ELLIPSE study

P.-M. Llorca[1]*, L. Mékaoui[2], M. Rotharmel[3], P. de Maricourt[4], C. Wicart[5], E. Gaudre-Wattinne[5] and J. Dupin[5]

[1]Department of Psychiatry, CHU Clermont-Ferrand, University of Clermont Auvergne, CNRS, Clermont Auvergne INP, Institute Pascal (UMR 6602), Clermont-Ferrand; [2]Mental and Brain Illness Clinic, Sainte Anne Hospital GHU Paris – Psychiatry and Neurosciences, Paris; [3]University Department of Psychiatry, Therapeutic Centre of Excellence, Institute of Psychiatry – Rouvray Hospital Centre, Sotteville-lès-Rouen; [4]Sainte Anne Hospital GHU Paris – Psychiatry and Neurosciences, Paris and [5]Medical Affairs, Janssen Cilag, Issy-les-Moulineaux, France
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.682

Introduction: Major depressive disorder (MDD) is the leading cause of disability worldwide. About one third of patients with MDD fails to achieve remission despite treatment and can be considered as Treatment-Resistant patients. Esketamine nasal spray (ESK) is indicated since 2019 in US and Europe for adults with Treatment-Resistant Depression (TRD), who have not responded to at least two different treatments with antidepressants in the current moderate to severe depressive episode. ELLIPSE is the first prospective observational study on ESK in real world conditions in France.
Objectives: The aim of the study is to describe the profile of all patients treated with ESK in real-world clinical practice, the modalities of the use of ESK, the patient management at the site of care and the efficacy and safety outcomes during 12 months after ESK treatment initiation for MDD patients.
Methods: ELLIPSE is a French prospective, multicenter, non-interventional study designed to describe patients presenting MDD treated with ESK, and for whom the decision to prescribe ESK is independent of the study. Data were collected from physicians as part of routine clinical practice and from patients via self-questionnaires.
Results: Thirty-one sites have included 211 MDD patients treated with ESK. The analysis will describe patient profiles (sociodemographic and disease characteristics, medical history, comorbidities), use of ESK at initiation and during study (reason for initiation, posology, frequency, administration, surveillance, treatment duration), safety profile (percentage of reported adverse events) and efficacy (MADRS response and remission rates over 12 months). The study results will be available in January 2025 and will be detailed in the poster presented at the conference.
Conclusions: ELLIPSE is the first large prospective French study providing real world evidence on patients treated with ESK, including patient's profile, condition of use of ESK treatment and follow-up efficacy and safety data. This study should confirm that ESK has its place in therapy for the treatment of MDD.

Machine Learning Prediction of Suicidal Ideation in Community-Based Older Adults using Deep Phenotypes

E. Moon[1]*, H. Lim[1] and K. Kim[1]

[1]Psychiatry, Pusan National University Hospital, Busan, Korea, Republic Of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.683

Introduction: Suicide is a major public health concern, especially among older adults. Early identification of individuals at risk of suicide is crucial for early intervention, which significantly improves prevention efforts. Early identification of individuals at risk of suicide is crucial for prevention.
Objectives: This study aimed to develop a model for predicting suicidal ideation in community-based older adults using deep phenotype data with machine learning classifiers.
Methods: A study investigating suicidal ideation in community-based older adults utilized a mobile assessment bus to collect data from 358 participants. Deep phenotype data, including Patient Health Questionnaire-9 (PHQ), Generalized Anxiety Disorder-7 (GAD), World Health Organization Quality of Life (WHOQOL), Perceived Stress Scale-10 (PSS) questionnaires, and 32-channel EEG recordings using the 10/20 system, were acquired. Of these participants, 238 completed all assessments. Suicidal ideation was defined by a score of 1 or higher on the ninth question of the PHQ-9. Data from both groups were compared, and features with an effect size of 1 or greater (Cohen's D) were selected for further analysis. Cohen's D. Machine-learning classifiers, including Support Vector Machine (SVM), Random Forest (RF), and Linear Discriminant Analysis (LDA) were employed to predict suicidal ideation using a 7:3 training-test split repeated 100 times to obtain performance metrics.
Results: Scores on the PHQ, GAD, and WHOQOL scales differed significantly, while the PSS data showed variations in all items except one between the group with suicidal ideation and the group without. Notably, analysis of the EEG data from eight brain regions identified disparities in 108 out of 248 features. Among all data, ten features with Cohen's D values exceeding 1 were identified, primarily consisting of questions directly related to themes of negative emotions. Using these features, the classification model achieved an

AUC of 0.8913, demonstrating strong predictive performance for suicidal ideation.

Conclusions: Our findings demonstrate the potential of deep phenotyping, even in community-based settings, to predict suicidal ideation in older adults. These insights can inform the development of suicide intervention systems. Additionally, refining predictive models to encompass broader mental health symptoms could solidify deep phenotyping as a crucial tool for early intervention in public healthcare.

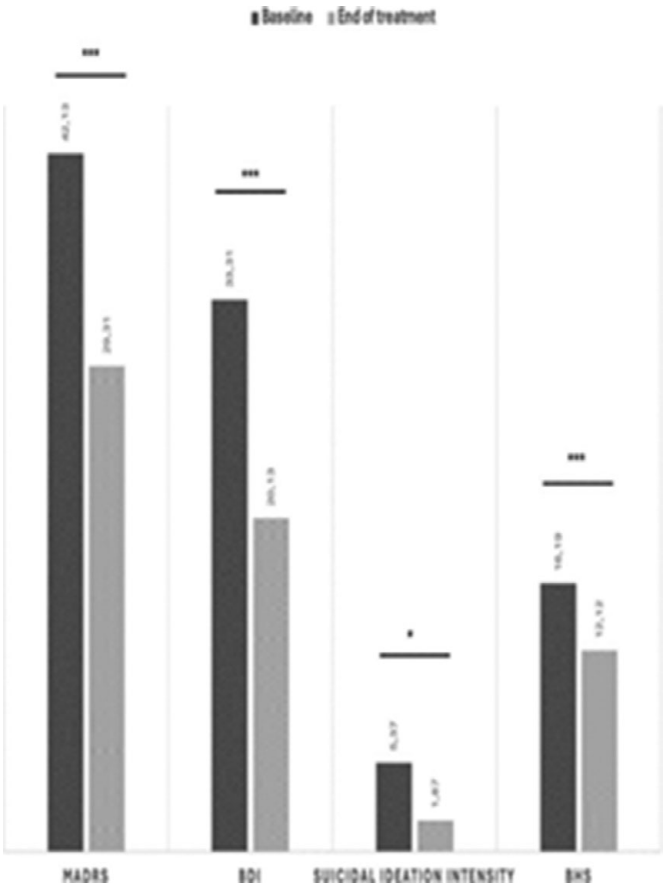
Efficacy of Esketamine nasal spray in treatment-resistant depression: impact on depressive symptoms,hopelessness and suicide risk: A real-world evidence study

M. Pompili[1]*, M. A. Trocchia[2], L. Longhini[2], E. Dispenza[2], C. Di Legge[2], S. Sarubbi[3], D. Erbuto[1] and I. Berardelli[1]

[1]Dept. of Neurosciences, Mental Health and Sensory Organs, Sapienza University of Rome; [2]Psychiatry Residency Training Program, Faculty of Medicine and Psychology, Sapienza University of Rome, Psychiatry Unit, Sant'Andrea Hospital and [3]Department of Human Neurosciences, Sapienza University of Rome, Viale dell'Università, Rome, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.684



Introduction: Treatment-resistant depression (TRD) is a condition associated with multiple severe implications and high suicide risk. Esketamine is a pharmacological agent approved by the FDA and EMA recommended for adults diagnosed with TRD. The glutamatergic mechanisms of depression are currently the subject of numerous studies. Esketamine has glutamatergic neuromodulatory properties to enhance the effects of selective serotonin and norepinephrine reuptake inhibitors. Furthermore, the anti-suicidal effect of esketamine represents a reason to explore its properties since managing suicide risk in patients with MDD is complex.

Objectives: The present observational, retrospective study aimed to assess the efficacy and tolerability of Esketamine in a real-world outpatient setting. A secondary objective was to explore the potential benefits on hopelessness and suicide risk(suicide ideation and suicide attempts) to establish future research directions that may enrich knowledge on the effects of esketamine on suicide risk in patients with resistant depression.

Methods: 20 patients diagnosed with treatment-resistant depression disorder were treated with Esketamine.Depressive symptoms (MADRS and BDI), suicide risk(C-SSRS), and hopelessness(BHS) were assessed. Repeated measures analyses were conducted to evaluate changes from baseline(T0) and 3-month follow-up(T1).

Results: 11 patients(60%)were females, and the average age of the sample was 49.40 (SD= 17.38). 9 patients(45%)were single,and 11 patients (55%) were employees.At baseline,11 patients(55%) reported suicidal ideation,and 2 patients(10%)attempted suicide in the previous 3 months. Of the 20 patients, 4 patients did not complete the treatment and were excluded from analyses. Results showed that depressive symptoms decreased at the end of treatment (t1) compared to baseline (t0).Specifically,both clinician (t=7.32; p<.001) and self-report (t=4.34;p<.001)measures show lower levels of depressive symptoms(MADRS t0=33.31±4.35vs.t1= 20.13 ±5.31,and BDI t0=42.13±7.97 vs.t1=29.31±9.96, respectively). About suicide risk, at baseline 11 patients reported some level of suicidal ideation while at (T1) 7 patients did; the difference was not statistically significant(p=.125);conversely,a significant decrease in suicidal ideation intensity was found (t=2.48,p<.05; t0=5.37±5.77vs.t1=1.87±3.51). Finally,patients also reported decreased hopelessness levels(BHS;t=3.97,p=.001; t0=16.19±3.12 vs. t1=12.12±4.27).

Image 1:

Conclusions: Our findings demonstrated a robust overall response regarding depressive symptoms after Esketamine in TRD. A notable response concerning suicide ideation intensity was also observed in patients with resistant depression; however, further studies are necessary to better investigate the role of esketamine in suicide prevention.

Effect of Sports Therapy Interventions on Severity of Symptoms in the Inpatient Treatment of Depression

M. Ziegenbein[1]*, M. Wendt[1] and K. Friedrich[1]

[1]Psychiatry and Psychotherapy, Wahrendorff Clinic, Sehnde, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.685

Introduction: Physical activity has been identified as a therapeutic intervention for the treatment of depressive disorders. It can be conducted as a standalone intervention or as a complementary therapy method within a multimodal treatment framework. Engaging in physical activity is important for maintaining physical and mental health. There is a need for research on the implementation of exercise therapy interventions that takes into account everyday clinical practice outside the controlled conditions in study protocols. Physical activity is particularly promoted in the context of sports therapy.
Objectives: Therefore, the objective of this study is to examine the impact of exercise therapy in a day clinic setting on depressive symptom severity and cardiovascular fitness.
Methods: The study sample includes patients with a primary diagnosis of depression who had completed a minimum of four and a maximum of nine weeks of inpatient treatment in a psychotherapeutic and psychosomatic hospital in Germany. Patients in the intervention group (IG) receive exercise therapy at least twice a week throughout their treatment, while patients in the control group received a maximum of 0.5 units/week of exercise therapy. As part of the multimodal treatment setting, the exercise therapy interventions in both groups include spinal exercises, equipment-based strength and endurance training, soccer and table tennis. The BDI-II is administered to both groups to assess the severity of depressive symptoms. Cardiovascular fitness of IG is monitored using a submaximal cycle ergometer aerobic fitness test (PWC test) at baseline and at the end of treatment.
Results: The total number of patients included in the analysis was n=37 in IG (male=78%, M age=42.05) and n=20 in CG (male=60%, M age=47,35). A significant reduction in the BDI-II score was observed in both the IG (M ΔBDI-II=-16.0, p<.001) and CG (M ΔBDI-II=-8.0, p<.05) from the beginning to the end of the treatment period. When comparing reduction in depressive symptoms between two groups, IG achieved statistically significant greater reduction in depressive symptoms compared to the CG (M ΔBDI-II=-8.0, p<.01). Participants in the IG showed a statistically significant improvement in performance, with an increase of 7 watts for the PWC130 and 12 watts for the PWC150 (p<.05), as measured by the submaximal cycle ergometer aerobic fitness test throughout treatment.
Conclusions: The integration of exercise therapy into a multimodal treatment framework was observed to positively impact both physical and mental health outcomes. Given the presence of physical comorbidities and relapses, further research should investigate the long-term impact of behavioral changes related to physically active lifestyle.

Addressing Mental Health Priorities in Mexican Youth: Developing a Primary Health Care and Psychiatry Model (MAP-PSI for its acronym in Spanish)

L. Diaz-Castro[1]* and N. Bautista-Aguilar[1]

[1]National Institute of Psychiatry Ramon de la Fuente, Mexico City, Mexico
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.686

Introduction: Depressive disorders among young people are a significant public health concern, particularly in underserved areas where access to mental health services is limited. The MAP-PSI model was developed to address this gap through a comprehensive approach that integrates promotion, prevention, and remote care strategies. Implemented in Ciudad Fernández, San Luis Potosí, Mexico, the model is designed to be adaptable and scalable, allowing it to meet the varying needs of different communities and leverage telemedicine and digital tools to extend mental health care.
Objectives: The MAP-PSI model aims to improve mental health outcomes for young people by providing an adaptable framework for addressing depressive disorders. Its goals are to enhance accessibility to mental health services in underserved areas, utilize bilingual and culturally sensitive materials, and integrate actions across various community settings. The model seeks to empower healthcare providers and decision-makers to implement effective, sustainable interventions that can be adapted for other health issues and locations.
Methods: The MAP-PSI model is implemented in four phases: Exploration-Planning: This phase involves community engagement, conducting needs assessments, and training local staff to ensure that the intervention is tailored to the specific needs of the community. Initial and Total Implementation: Active monitoring and real-time adjustments are made to the model to ensure its effectiveness and responsiveness to emerging needs. Sustainability: Focuses on maintaining and expanding the model's reach through continuous improvement processes, ensuring long-term impact and adaptation.
Results: Key components of the model include psychoeducation, psychological support, telepsychiatry, and community-based promotion and prevention efforts. The use of bilingual and culturally sensitive materials is emphasized to cater to diverse populations, including indigenous groups. Integration across primary health care centers, schools, and community settings enhances the support for mental health and prevention of depressive disorders.
Conclusions: The MAP-PSI model demonstrates promising social returns on investment by effectively addressing depressive disorders through a scalable and adaptable framework. Its integration of telemedicine and digital tools enhances accessibility to mental health care in underserved areas, while its culturally sensitive approach ensures relevance across diverse populations. The model's phased implementation framework supports both immediate effectiveness and long-term sustainability. The MAP-PSI model offers a valuable guide for health care providers and decision-makers, with the potential for adaptation and expansion to other health issues and regions, thereby contributing to improved mental health outcomes and sustainable intervention practices.

Effectiveness of Guided Self-Help Versus Internet-Delivered or Face-to-Face Cognitive Behavioral Therapy for Depression and Anxiety: a Randomized Controlled Non-Inferiority Trial of the Finnish First-Line Therapies –Initiative (FLT-Step)

E.-E. Helminen[1]*, K. Mikkonen[1], S. I. Saarni[1], K. Mattila[1], T. Rosenström[2], E. Isometsä[2] and S. E. Saarni[1]

[1]Psychiatry, HUS Helsinki University Hospital and [2]University of Helsinki, Helsinki, Finland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.687

Introduction: Depression and anxiety are among the most prevalent mental health conditions, particularly in Western countries. Access to effective treatments, such as cognitive behavioral therapy (CBT), in publicly funded primary care settings is often insufficient.
Objectives: This study aims to evaluate, within a non-inferiority framework, the effectiveness and cost-effectiveness of three treatment modalities for depression and anxiety within the Finnish public healthcare system: 1) a stepped care model, which involves sequential guided self-help (GSH) followed by face-to-face CBT for non-responders; 2) internet-delivered CBT (iCBT); and 3) face-to-face CBT.
Methods: Our objective is to recruit 948 adults (16+ yrs) exhibiting symptoms of depression (scoring ≥10 on the Patient Health Questionnaire, PHQ-9) and 948 adults exhibiting symptoms of anxiety (scoring ≥10 on the Generalized Anxiety Disorder scale, GAD-7). These participants should be suitable for step 1 or step 2 treatments, such as GSH, iCBT or CBT, within the Finnish public healthcare system. Individuals currently receiving psychological treatment, those with severe suicidal ideation, cognitive impairment, or those with substance abuse issues will be excluded from the study. Participants will be randomly assigned to one of three groups: GSH, iCBT, or face-to-face CBT. Those who do not respond adequately to GSH will be stepped up for further treatment with face-to-face CBT. Participants will complete symptom measures, such as PHQ-9, GAD-7, measures of function, work ability and social support at various stages over the course of the study to track changes in their mental health. The trial and follow-up period will span 5 years. In addition to data collected from the study participants, the study incorporates direct and indirect healthcare, social care, employment, and societal cost data from Finnish national registries. These registries will also be utilized to create population-matched controls for the study participants. The study will be conducted within several wellbeing service counties in Southern Finland and Western Finland. It is part of the Finnish First-Line Therapies –initiative in Finland's public healthcare system.
Results: Recruitment of study participants began in autumn 2024 and is expected to take approximately one year. Initial results are anticipated by 2026. The study protocol has been registered in the ISRCTN registry prior to the commencement of participant recruitment. The study is primarily funded by grants from the Ministry of Social Affairs and Health in Finland (VN/29619/2023 and VN/29613/2023).
Conclusions: The study aims to improve access to effective, evidence-based treatments for depression and anxiety within the public healthcare system.

Therapy Sessions as Part of the Prenatal Care Programme

A. Mihai[1]* and M. R. Isabela[2]

[1]Psychiatry, University of Medicine, Pharmacy, Science and Technology George Emil Palade Targu Mures and [2]Psychiatry, Mureș County Hospital, Targu-Mures, Romania
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.688

Introduction: Prevention is key to maintain a healthy lifestyle and to ensure a positive outcome of any given condition, especially in such a vulnerable one, as is pregnancy. The progress made in prenatal care in the last century is astounding and professionals nowadays are able to provide state of the art investigations and inventions throughout pregnancy and even before, but there is a dire need to address the mental health approach of the soon-to-be mothers. Since studies have shown the link between mother's emotions and the child's well-being, providing support in order to maintain a good mental health status should be part of the prenatal care programmes.
Objectives: The initial hypothesis is that pregnancy is a delicate period for the mother to be, therefore anxiety levels can be high or prenatal depressive episodes can occur in the absence of good psychological support. We aim to prove that integrating psychotherapy as part of the prenatal care programmes has benefits for both mothers and child and can significantly reduce the struggle of battling these symptoms on one's own.
Methods: We launched an online questionnaire on groups and sites that targeted pregnant women or women who have just given birth. The questions were designed to address the anxiety and/or depressive symptoms throughout the pregnancy, the support they received from the health care providers and the impact these had on how they handled the pregnancy period. Anxiety symptoms were assessed using the HAM-A scale, meanwhile for depressive symptoms we used PHQ9 questionnaire. The study was conducted anonymously and was approved by the local ethics committee.
Results: We received 200 answered questionnaire, from which 189 were valid and relevant to the study.
The results showed that the majority of pregnant women (83%) have struggled with anxiety and/or panic attack throughout the pregnancy and the prenatal care appointments proved insufficient to alleviate their concerns. Most of them (94%) turned to the internet for answers, which was an aggravating factor for the symptoms. The impact these symptoms had on their pregnancy varied from tensions between them and their partners, insomnia, feelings of worthlessness and irritability to moderate depressive episodes. Almost all the respondents (91%) have answers affirmatively to the proposal to undergo a few therapy sessions to manage

these symptoms, if they were to be part of the prenatal care programme.
Conclusions: Pregnant women are at risk for various mental health issues which can be prevented with proper care, thus addressing further risk for both the mother and the baby. The need for integrating therapy in prenatal care programmes could have a great impact on the outcome of the pregnancy and even in women desire to bear children.

Trauma matters! Trauma-informed care among allied health professionals working with children and youth and its associations with personal factors

A. Stern[1]*, L. Lamash[2] and N. Ghanem[2]

[1]Occupational Therapy, Ben-Gurion University of the Negev, Beer Sheva and [2]Occupational Therapy, University of Haifa, Haifa, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.689

Introduction: Childhood trauma can significantly impact development, function, and well-being. Allied health professionals often support individuals exhibiting trauma-related signs, but the extent of trauma-informed care (TIC) understanding and application remains unclear. Moreover, secondary traumatic stress (STS) is a significant concern for professionals who treat traumatized children and youth. Thus, it is essential to provide TIC training to these professionals while also addressing the potential effects of STS.
Objectives: The current study mapped the knowledge of trauma, the perceived relevance of TIC, and its implementation among allied health professionals working with children and youth. It also examined the relationships between knowledge of trauma, TIC perceived relevance and implementation, and relevant personal factors (resilience, self-compassion, and empathy).
Methods: 176 allied health professionals (nutritionists and occupational, speech, and physical therapists) answered an online survey including a demographic questionnaire, Trauma-Informed Approach Questionnaire, Connor-Davidson Resilience Scale, Self-Compassion Scale, and Interpersonal Reactivity Index. Descriptive statistics and ANOVA were used to describe the sample and assess differences between knowledge, attitudes, and implementation. Pearson correlations were used to assess relationships with personal factors.
Results: Significant differences were found between trauma knowledge, TIC relevance perception, and TIC implementation among the entire sample, $F(2, 352) = 127.5$, $p<.001$, $\eta^2= 0.43$. Perception of TIC relevance was higher than knowledge of trauma (p<.001) and TIC implementation (p<.001). Positive correlations were found between resilience and knowledge of trauma ($r=.22$, p<.01), TIC perception relevance ($r=.17$, $p<.05$), and TIC implementation ($r=.23$, $p<.05$). Self-compassion was positively correlated with knowledge of trauma ($r=.18$, $p<.05$) and TIC implementation ($r=.22$, $p<.01$). Perspective-taking (empathy) was positively correlated with knowledge of trauma ($r=.15$, $p<.05$), perception of TIC relevance ($r=.39$, $p<.01$), and TIC implementation ($r=.31$, $p<.01$), and empathic concern was positively correlated with perception of TIC relevance ($r=.33$, $p<.01$).
Conclusions: The findings highlight the limited knowledge of trauma and TIC implementation among allied health professionals, emphasizing the lack of TIC training. Resilience, self-compassion, and empathy can be strategies to cope with treating children and youth who have experienced trauma and prevent STS.

Community mental health centres in Slovenia: assessment of the situation and needs

N. Petkovšek[1], V. Švab[1,2]*, U. Juhart[1] and R. Zupan[2]

[1]Mental health center, Health Center Logatec, Logatec and [2]Mental health, National Institute for Public Health, Ljubljana, Slovenia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.690

Introduction: Mental health reform was accepted in Slovenia in 2018 to provide accessible community treatment and care regionally for 40-70000 population. The implementation took place mostly with establishment of community mental health centers (CMHC), which included arround 20 000 patients in 16 community centers for the adult population. These CMHCs provide triage, needs assessment and treatment plans. The National Mental Health Plan did not adress the development of rehabilitation services. The institutional costs of treatment and care were not reduced, as well as not the number of institutional beds.
Objectives: To assess the development of CMCH's in Slovenia on the grounds of the data from the CMHC Logatec.
Methods: The data about 5761 patients included in the treatment process in one of the CMHCs were gathered regarding basic demographic data, diagnosis and treatment mode, including the definition of care coordination.
Results: 2654 patients were treated in the home environment. Medical nurses were coordinating treatment in the majority of these patients. Occupational therapist, social worker and psychiatrists were part of the team in this group. 816 patients in this group were diagnosed with dementia and had also somatic ilness. 1011 were diagnosed with schizoprenia or other psychotic disorders. 3107 patients were treated in the outpatient care, the majority of them by psychologists. Psychiatrists and social worker were included in these care coordinating teams. 1219 of them were diagnosed with depressive and 1001 anxiety disorders.
Conclusions: Community care teams in Slovenia included around 20 000 patients in three years time. The majority of these, specifically in Logatec are diagnosed with schizophrenia, dementia, depressive and anxiety disorders. Immediate access to service is still granted, with exception of psychological treatment which does not reach everybody in need in time. Development of CMCH's should be led by needs assesment on the ground of developing data. It's already obvious that increase of the number of psychologists to

improve psychological assistance to people with cognitive decline and for young people in severe but mostly manageable psychological crisis is needed.

The relationship between lifestyle and negative affect. Executive functioning and emotional regulation as mediators.u

I. Ursu[1,2*], R. S. Balazsi[1] and A. Ursu[1]

[1]Psychology, University Babes-Bolyai and [2]Psychiatry, Emergency Hospital of Neurology and Psychiatry, Cluj-Napoca, Romania
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.691

Introduction: The increasing prevalence of mental health issues presents a significant challenge for modern societies. There's a crucial need for quick, affordable interventions that can be widely implemented by practitioners to support as many individuals as possible.
Objectives: In this paper we aimed to investigate the mediating role of executive functions and emotional regulation in the relationship between sleep quality and physical activity, on one hand and negative affect, on the other.
Methods: Our proposed model is a serial mediation model, with executive functions as the first mediator and the two components of emotional regulation as the second mediator. We collected data from 286 participants who completed a series of questionnaires.
Results: The initial model did nit fit the data well. Therefore, we added two paths: the direct relationship between sleep quality and negative affect and the direct relationship between executive functions and negative affect. The final model had a very good fit with the data. Thus, both the hypotheses regarding the direct relationships and those regarding the indirect relationships are supported by the data.
Image 1:

Note: AN-negative affect, DAS_A-anxiety, DAS-D-depression, DAS_S-stress, S_CTR-self-control, ATEN-atention., PLAN-planification, FE- executive function, MET_T-level of physical activity, PSQI-sleep quality, RESTR-cognitive restructure, SUPR-emotional suppression.

Image 3:

Figure 3. *Modified structural model*

Note: AN-negative affect, DAS_A-anxiety, DAS-D-depression, DAS_S-stress, S_CTR-self-control, ATEN-atention., PLAN-planification, FE- executive function, MET_T-level of physical activity, PSQI-sleep quality, RESTR-cognitive restructure, SUPR-emotional suppression.

Conclusions: The results highlight the importance of interventions aimed at improving sleep quality and promoting physical activity. These interventions can serve to promote optimal mental health in both clinical and non-clinical populations. Additionally, this research provides a basis for developing effective strategiesfor the prevention and treatment of these populations.

Patient Journeys and Outcomes in Mental Healtcare Systems in Europe – Narrative Review and Study Protocol for a Trans-European Comparison

H. F. Wiegand[1,2]*, O. Tüscher[1,2] and K. Adorjan[3,4]

[1]Department of Psychiatry, Psychotherapy and Psychosomatics, University Medicine Halle, Halle (Saale); [2]Department of Psychiatry and PSychotherapy, University Medicine Mainz, Mainz, Germany; [3]Department of Psychiatry and PSychotherapy, University of Bern, Bern, Switzerland and [4]Department of Psychiatry and PSychotherapy, LMU Munich, Munich, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.692

Introduction: Mental healthcare systems in Europe differ greatly in terms of access and care settings. Whereas comparisons of the structures partly exist (e.g. REFINEMENT project), not much is known neither about the patient journeys for specific disease entities nor about outcomes of these differently organized systems.
Objectives: The first objective is to review the existing literature on structural differences in mental healthcare sytsems in Europe. The second objective is to discuss options for studies that gather differences in patient journeys and outcomes for specific disease entities.
Methods: Narrative review about structural differences in mental healthcare in Europe and discussion of a study protocol for assessing patient journeys for 6 important disease entities (Severe Major Depressive Disorder, Schizophrenia, Behavioural disorders in Dementia, Borderline Personality Disorder, PTSD, Alcohol Addiction).
Results: European mental healthcare systems differ greatly in terms of structures of mental healthcare provision. E.g. Belgium had 141 hospital beds per 100,000 inhabitants, Germany 131, the Netherlands 112, Switzerland 95, Austria 75, and Denmark 5 (eurostat, 2024a). However, what these numbers mean for the patient journeys and for the systems outcomes is unclear. We discuss an approach for examining prototypical patient journeys for the above-mentioned disorders and for comparing their outcomes in terms of quality of life and global psychosocial functioning.
Conclusions: We are looking for European partner institutions for establishing a mental health systems research network. The goal is to set up studies that allow to compare patient journeys and outcomes within the differing European Mental Healthcare Systems as a basis for mutual learning from best practice examples.

Studying loneliness and its impact on mental health among University students: the SONDEU Project

A. Calvo[1]* and E. Lara

Personality, Assesment and Clinical Psychology Department, Universidad Complutense de Madrid, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.693

Introduction: The challenge of loneliness underlines the need for studies that allow us to analyse and understand this phenomenon, particularly in vulnerable groups. Although loneliness can occur at any stage of life, it seems to be more prevalent during phases of transition, where changes in social relationships are frequent (Mund et al., 2020). In the younger population, a significant restructuring of social life is observed, with peer relationships becoming more central while family ties become less prominent. This often coincides with key life transitions such as change of residence, first romantic relationships, work experiences, etc. (von Soest et al., 2020). This is especially noticeable during the university stage, a period often accompanied by academic pressure due to personal, familial or societal expectations and/or needs. Furthermore, this stage is especially critical from a mental health perspective, as most mental health problems appear for the first time before the age of 25.
Objectives: 1) To analyse the impact that loneliness has on the student community at the Complutense University of Madrid (UCM). 2) To find out the prevalence and types of loneliness as well as its association with different problems of mental health.
Methods: This study follows a two-phase mixed-methods approach. In the first phase, two focus groups were conducted to explore the definition and characteristics of loneliness in-depth. The convenience sample consisted of 8 to 10 students per focus group from different educational levels and academic disciplines. A pre-designed guide with open-ended questions facilitated the session (e.g., "Reflecting on your university experience, what situations or experiences have made you feel lonely?"). In the second phase, a cross-sectional observational study was conducted. While we estimated a sample size of 246 participants to explore the prevalence of loneliness, we aim to obtain a representative sample of students from the UCM. The following measures were included: loneliness (frequency, type), mental health (depression, anxiety, psychotic experiences, suicidal behaviour), well-being and social relationships, academic performance, non-behavioural addictions and lifestyle. Data is being processed and analysed using appropriate statistical and qualitative analysis software. This study has received ethical approval from the participating institution.
Results: Data from the focus groups and the online survey were compared from different educational levels and academic disciplines to explore characteristics of loneliness and mental health problems.
Conclusions: This study seeks to gain a deeper understanding of loneliness among university students. These findings aim to promote changes that integrate a new form of care and promotion of mental health in this group (i.e., identification, prevention and management of loneliness) as well as to encourage further research in this area.

Comparing mental health levels between caregivers of patients with severe mental disorders and caregivers of patients with rare genetic diseases

M. Di Vincenzo[1]*, F. Guida[1], S. Calamaro[1], R. Murolo[1], B. Prota[1], M. Luciano[1], G. Limongelli[2], G. Sampogna[1] and A. Fiorillo[1]

[1]Department of Psychiatry and [2]Inherited and Rare Cardiovascular Disease Unit, Department of Translational Medical Sciences, University of Campania "Luigi Vanvitelli", Naples, Italy

*Corresponding author.
doi: 10.1192/j.eurpsy.2025.694

Introduction: Severe mental disorders and rare genetic diseases are chronic and highly disabling conditions requiring continuous assistance by caregivers, whose personal and social burden may result in mental health problems.
Objectives: The current study aims to compare objective and subjective burden as well as levels of general well-being, anxiety, depressive symptoms, PTSD symptoms, sleep quality and suicidality between caregivers of patients with severe mental disorders, caregivers of patients aged 0-18 with rare genetic diseases, and caregivers of patients aged 50-85 with rare genetic diseases.
Methods: Caregivers of patients with severe mental disorders were recruited at the Department of Psychiatry of University of Campania, Naples, if they were more than 18 and released consent. Caregivers of all patients with rare genetic diseases were recruited at the Inherited and Rare Cardiovascular Disease Unit of University of Campania, Naples, if they were more than 18 and released consent. Caregivers' levels of personal and social burden, anxiety, depressive symptoms, PTSD symptoms, sleep quality and suicidality were assessed through standardized tools and compared between groups by carrying out analyses of variance.
Results: Seventy-seven caregivers were included, mostly women (74.0%) with a mean age of 52.2±12.5 years. Caregivers of patients with severe mental disorders were mainly mothers (31.8%) or partners (31.8%) of patients, showing the highest levels of subjective burden, as well as avoidance and need to be informed about the illness adopted as problem-solving strategies. Caregivers of patients aged 0-18 with rare genetic diseases were mainly mothers of patients (76.5%), reporting the highest levels of received support and PTSD symptoms. Caregivers of patients aged 50-85 were usually partners of patients (52.4%), who showed the lowest levels of need to be informed about the illness and PTSD symptoms.
Conclusions: Caregivers of patients suffering from chronic and disabling diseases such as severe mental disorders and rare genetic diseases are prone to develop mental health problems due to the persistent exposure to high levels of personal and social burden. To this extent, family psychosocial interventions may be effective strategies to be implemented in order to relieve the levels of burden, by taking into account the features of patient's disease.

Beyond symptoms: How mental health competencies shape everyday well-being among psychiatric patients

F. Pongracz[1], V. Zabo[1,2,3], D. Erat[4], A. Vargha[1,5], A. Vincze[1,2,6], J. Harangozo[7,8], M. Ivancsics[6], J. Farkas[1,6], G. Balogh[6], J. Bognar[9], E. Nagy[1] and X. Gonda[10]*

[1]Faculty of Education and Psychology, Institute of Psychology; [2]Doctoral School of Psychology, Eotvos Lorand University; [3]Faculty of Medicine, Institute of Behavioural Sciences, Semmelweis University, Budapest; [4]Department of Sociology, University of Pecs, Pecs; [5]Person- and Family-Oriented Health Science Research Group, Faculty of Humanities and Social Sciences, Institute of Psychology, Károli Gáspár University of the Reformed Church in Hungary; [6]Nyiro Gyula Hospital, National Institute of Psychiatry and Addictology; [7]Community Psychiatry Centre, Semmelweis University; [8]Awakenings Foundation; [9]Department of Pediatrics and [10]Department of Psychiatry and Psychotherapy, Semmelweis University, Budapest, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.695

Introduction: Just as our bodies have immune systems to defend against harmful biological agents, our souls also need psychological "immune competencies" to cope with stress. These competencies include effective emotional, psychological, social and spiritual functioning, resilience, creative and executive efficiency, self-regulation and savoring, the ability to enjoy positive experiences.
Objectives: The aim of the present study was to investigate whether the mental health competencies, the symptoms of mental disorder, or the interaction of the two have a stronger predictive power on subjective well-being among Hungarian adult psychiatric patients.
Methods: The psychiatric sample of 129 patients (44 men, 85 women) was recruited in a cross-sectional design in four Hungarian health care facilities. Participants completed the Symptom Checklist-90-Revised, the Mental Health Test and six well-being questionnaires.
Results: Mental health competencies are stronger predictors of the three indicators of well-being ($\beta = 0.61; 0.79; 0.51$ $p < 0.05$) than mental disorder symptoms ($\beta = 0.17; 0.12; 0.25$, $p < 0.05$). Including both mental health competencies and mental disorder symptoms in a regression model more accurately predicts indicators of well-being (BIC = 310; 359.7; 170; AIC = 289; 337.3; 148.3; $R^2 = 0.74; 0.52; 0.58$, $p < 0.05$) than either the effect of the two separately (BIC = 310.3; 365.4; 170.2; AIC = 291.1; 345.8; 151.1; $R^2 = 0.73; 0.48; 0.56$, $p > 0.05$) or the effect of their interaction (BIC = 314.9; 363.6; 173.6; AIC = 290.3; 338.4; 149.1; $R^2 = 0.74; 0.52; 0.57$, $p > 0.05$). Mental health competencies were positively ($B = 0.88; 1.64; 0.54$, $p < 0.05$) while mental disorder symptoms were negatively ($B = -0.50; -0.28; -0,17$, $p < 0.05$) related to indicators of subjective well-being.
Conclusions: The results underscore the potential of mental health competencies as protective factors that can enhance well-being and restore daily functioning even in the presence of mental disorder symptoms.

Patterns of service use in a culturally adapted NAVIGATE program for first-episode psychosis and their association with clinical and functional outcomes

G. Hoter Ishay[1,2]* and D. Roe[2]

[1]Occupational Therapy, Ono academic college, Kiryat Ono and [2]Community Mental Health, University of Haifa, Haifa, Israel
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.696

Introduction: NAVIGATE, is a comprehensive manual based intervention developed in the US for young people experiencing a first episode psychosis (FEP) . The intervention is based on four main service components: Individual Resilience Training (IRT), supported employment and education (SEE), family psychoeducation (FEP) and medication management.
Objectives: To describe the process of implementing NAVIGATE in Israel with an emphasis on cultural adaptation, fidelity, patterns of use and their relation to outcomes.
Methods: Between 2017-2021 demographic and diagnostic, service utilization data and ratings of functioning and symptoms were collected from clinical registries of 142 NAVIGATE participants.
Results: Most participants were males (70%), aged 23.5 (SD 5.5, Range 16-43). On average, participated in the program over a year. IRT was the most utilized intervention (M=23, SD 11.51). Overall, three clusters of program usage were found. Number of sessions and their frequency were highly correlated. Number of family psychoeducation meetings showed the highest correlation with improvement overtime in functioning and symptoms severity. Program Fidelity rates ranged from 2.8 to 3.3 (range 0-4).
Conclusions: The NAVIGATE program in Israel demonstrated significant clinical and functional outcomes across all service use patterns. NAVIGATE was formally offered for two years and included four components, in reality, service users attended less than what was offered. It is possible that when an effective comprehensive team-based intervention is offered flexibly to meet the often rapid changes needs of young people with FEP, the actual use is less than one might expect, which has important implications for policy and practice.

EPP423

Using a co-design approach to develop, implement, and evaluate a Preventative Online Mental Health Program for Youth (POMHPY)

S. Kim[1,2*] and E. Moghimi[2,3]

[1]Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton; [2]Waypoint Research Institute, Waypoint Centre for Mental Health Care, Penetanguishene and [3]Psychiatry, Queen's University, Kingston, Canada
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.697

Introduction: From March 2020 to 2021, the risk of youth developing a mental health issue increased by 50% in Canada. To address the detrimental effects of the COVID-19 pandemic, this project collaborated with youth and community partners in Ontario, Canada, to co-design a Preventative Online Mental Health Program for Youth (POMHPY) focused on improving mental, physical, and social well-being.
Objectives:
(1) To co-design a preventative online mental health program tailored to the needs of Ontario youth. (2) To evaluate the program's efficacy in improving mental well-being and health-related quality of life. (3) To engage youth in the development and continuous improvement of the program.

Methods: Initially, literature reviews were conducted to identify evidence-based programs that could be integrated into POMHPY. Surveys and focus groups were used to capture youths' mental health concerns and program needs. The findings were presented to community partners for additional feedback and refinement of the program. A second survey and focus group explored the likelihood of program use and piloted the first session. Subsequently, 53 youths (mean age=19.15) participated in the POMHPY program during the summer of 2023. Pre-, post-, and follow-up surveys measuring mental well-being were administered. Preliminary descriptive statistics and t-test analysis were conducted to measure the program's efficacy. A subset of participants (n = 21) attended 90-minute focus groups to discuss program perceptions, perceived benefits, impact on personal life, and areas of improvement.
Results: Youths' mental well-being, measured by the Warwick-Edinburgh Mental Well-being Scale, significantly improved after the completion of the program [t (24) =-2.91, p=.008]. Health-related quality of life, measured by the AqoL-6D, also significantly improved [t (6) =-3.34, p=.016]. These improvements were maintained one month after completing the program. Participants viewed the skills and strategies learned in POMHPY as beneficial in improving their stress and well-being. Peer facilitators in the same age range as participants contributed to meaningful discussions and interactive activities that contrasted with a lecture-style learning environment. Suggestions for improvement included flexible scheduling, increasing reminders, and enhancing understanding of program components.
Conclusions: Preliminary analysis supports the program's efficacy in improving mental well-being and health-related quality of life. Participants also reported a positive experience with the program and suggested improvements for integration. The program will be scaled nationally in the next phase, ensuring broader access to preventative mental health care for youth across Canada.

Transforming Mental Health Care – Policy Implementation

H. Prata Ribeiro[1,2,3*], P. Mackay[1], E. Azevedo[1] and N. Bettencourt[1]

[1]Saúde Mental, Estrutura para a Saúde Mental dos Açores, Angra do Heroísmo; [2]Serviço de Psiquiatria, Hospital Beatriz Ângelo, Loures and [3]Medicina, Católica Medical School, Lisboa, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.698

Introduction: The Autonomous Region of the Azores faced considerable challenges in providing comprehensive, efficient, and integrated mental health care services, exacerbated by geographical isolation, resource constraints, and the absence of a cohesive system for referrals and quality assessment in mental health care.
Objectives: Despite the recognized need, the integration of mental health services into primary health care (PHC) and the broader health system in the Azores was fragmented. Key issues included lengthy waiting lists, inadequate referral systems between primary care and specialized psychiatric services, and a lack of standardized quality assessment and performance indicators for mental health care. Additionally, there was a significant need for community mental health teams, emergency management of agitated patients, and comprehensive training for health professionals in psychiatric care.

Methods: Through collaborative efforts, the region achieved notable advancements, including the creation of referral criteria from PHC to psychiatry services, structuring inter-service referrals, reactivation of Community Mental Health Teams, and establishment of a "Physician's Bank." Noteworthy was the elimination of a waiting list of over 1,000 patients and the development of quality assessment and performance indicators. The construction of a courtyard for involuntarily hospitalized patients and the creation of an emergency room on Faial Island further exemplified the tangible improvements in patient care and system efficiency. Training programs were extensively implemented across various professional groups, enhancing the capacity for mental health care delivery at all levels.
Results: The integration efforts underscored the value of cross-sector collaboration, stakeholder engagement, and the adaptation of models like the SURE framework and COM-B theory to address the multifaceted barriers to mental health care integration. Key facilitators included the development of guidelines, training, and clinical supervision, alongside innovative approaches to public health interventions.
Conclusions: The transformative work in the Azores exemplifies how integrated care models, supported by strategic collaborations and policy reforms, can significantly enhance mental health service delivery in geographically isolated regions. It underscores the importance of systemic approaches to training, infrastructure development, and stakeholder engagement in achieving sustainable improvements in mental health care.

The role of TMS in the clinical trajectory of patients with resistant Obsessive Compulsive Disorder Systematic Review

U. Anyeji, [1]*, E. O. Molokwu[2] and O. Alli-Balogun[1]

[1]Adult Psychiatry, BronxCare Health System, Bronx, United States and [2]Psychiatry, Windsor, Canon, Saint Kitts and Nevis
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.699

Introduction:

- Obsessive- Compulsive Disorder (OCD) is a neuropsychiatric illness affecting 2-3% of the United States population during their lifetime. It is a highly prevalent chronic disorder, often refractory to treatment, an understanding of the pathophysiology of OCD is crucial to optimize treatment. The most common comorbid diagnosis is major depressive disorder (MDD). In 2018, the US Food and Drug Administration cleared the treatment of resistant OCD with high frequency deep repetitive transcranial magnetic stimulation (dTMS) over the dorsomedial prefrontal and anterior cingulate cortices (DMPFC-ACC) with the H7 coil based on the efficacious results of a multi-center study. Compare to H7 coil, H1 coil which is approved for the treatment of resistant MDD, targets and stimulate the left prefrontal cortex more than the medial and right prefrontal cortices.
- Carmi L, Tendler A, Rodrigues da Silva D,

Objectives: To assess the effect of TMS in patients with refractory OCD
Methods: We conducted literature review search on treatment-specific for OCD on four databases, i.e google scholar, PubMed, PsycINFO and Mount Sinai's Levy Library.
Results: The meta-analysis combined the results of individual randomized controlled trials (RCTs) to evaluate the effectiveness of repetitive transcranial magnetic stimulations (rTMS) on obsessive-compulsive disorder (OCD). It showed that rTMS were moderately effective in reducing OCD symptom severity (studies indicated a medium-sized effect, Hedges' g = 0.59-0.65) and a threefold augmentation of treatment effects as compared with sham conditions. Studies also reported a marked heterogeneity in treatment response, which appeared to be particularly seen in patients with comorbid depression. Clinical improvement in depression was associated with greater reductions in OCD symptoms.
Certain rTMS protocols, including low-frequency stimulation (LF-rTMS) over the dorsolateral prefrontal cortex (DLPFC) and supplementary motor area (SMA), consistently showed more effects. Longer session durations and targeted stimulation of non-DLPFC regions, such as the orbitofrontal cortex and pre-SMA, were also associated with more positive outcomes.
But there are limitations - These studies were small, heterogeneous, and prone to publication bias, and few studies reported serious side effects, though some protocols especially those using high-frequency stimulation yielded higher rates of adverse effects.
Conclusions: To conclude, rTMS use as a new therapy for treatment-resistant OCD, particularly OCD comorbid with depression, is promising. However, due to study design inconsistencies and limited statistical power in individual trials, the quality of evidence is currently low. Studies using this approach need further improvement and more evidence to refine stimulation parameters better, increase our understanding of the underlying mechanisms, and confirm sustained efficacy.

Clinical correlates of plasma ghrelin and LEAP-2 concentrations in Eating Disorders and Obesity

I. Baenas[1,2,3,4]*, L. Camacho-Barcia[1,2,3], R. Granero[2,3,5], S. Tamarit[6], S. Jiménez-Murcia[1,2,3,7,8] and F. Fernández-Aranda[1,2,3,7]

[1]Clinical Psychology, Bellvitge University Hospital; [2]Eating and Addictive Behaviours, Neuroscience Program, Bellvitge Biomedical Research Institute (IDIBELL); [3]CIBER Physiopathology of Obesity and Nutrition (CIBERobn), Instituto Salud Carlos III; [4]Doctoral Program in Medicine and Translational Research, University of Barcelona; [5]Psychobiology and Methodology, Autonomous University of Barcelona; [6]University of Barcelona, Barcelona, Spain; [7]Clinical Sciences, School of Medicine and Health Sciences and [8]Psychology Services, University of Barcelona, Barcelona, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.700

Introduction: Hormones such as ghrelin and the recent described human liver expressed antimicrobial peptide-2 (LEAP-2) play a pivotal role in regulating food intake and energy metabolism. In this

context, their aberrant functioning has been suggested as a mechanism underlying the pathophysiology of eating disorders (ED) and obesity. Considering the high comorbidity between binge spectrum disorders (BSD) and obesity, whether this dysfunction could be a potential shared neurobiological mechanism remained underexplored.
Objectives: To analyze plasma ghrelin and liver expressed antimicrobial peptide-2 (LEAP-2) concentrations in fasting among individuals with obesity (OB), with and without an eating disorder (ED), and compare them with a group of healthy controls (HC). Besides, to assess associations between these concentrations, psychopathological variables, and body mass index (BMI) in the clinical sample with OB.
Methods: The sample comprised 162 adult women (67 OB-ED, 35 OB+ED, and 62 HC). Peripheral blood samples, eating psychopathology, trait impulsivity, food addiction (FA), fat mass, and BMI were collected. The between-group comparisons were performed using analyses of covariance (ANCOVA), adjusting for age and fat mass, and the link between variables was evaluated through correlation and path analyses.
Results: Individuals with OB (with and without an ED) showed lower significant ghrelin concentrations than HC ($p<.001$). The OB +ED group reported significantly higher eating psychopathology, trait impulsivity, and FA than the OB-ED and HC groups. In the OB+ED group, LEAP-2 concentrations positively correlated with BMI, fat mass, novelty seeking, and FA scores. The path analysis showed that higher LEAP-2 levels and FA scores were linked to more severe eating psychopathology
Conclusions: The results suggest an interplay between biological and clinical factors that contribute to delineate vulnerability pathways in ED and OB, which could help fit more tailored therapeutic approaches.

Involuntary Treatment in Patients with Eating Disorders

R. F. Dionísio[1]*, C. Portela[1], D. Areias[1], S. M. Sousa[1], C. Fonseca[1] and C. P. Desport[1]

[1]Hospital de Magalhães Lemos, Unidade Local de Saúde de Santo António, Porto, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.701

Introduction: Eating disorders, in particular Anorexia Nervosa (AN), are serious psychiatric disorders with a chronic course and high levels of disability and mortality. These disorders are characterized by a misrepresentation of body image and intense fear of putting on weight, leading to cognitive distortions related to food and weight control, as well as dysfunctional behaviors aimed at weight loss.
Objectives: The aims of this paper are to provide a summary of the current literature concerning involuntary treatment in patients with eating disorders and to assess whether there is a difference in terms of baseline characteristics and treatment outcomes between patients treated both voluntarily or involuntarily.
Methods: Relevant articles were identified by searching the following terms: "treatment refusal", "involuntary/compulsory/coercive/forced treatment/admission", "eating disorders", "anorexia nervosa", "bulimia nervosa". Research was restricted to articles concerning humans and published between 2014 and 2024 in English.
Results: The treatment of eating disorders consists in a combination of weight control/weight gain methods and psychotherapy, as well as the treatment of organic complications associated with starvation and low body weight.
Involuntary treatment is usually intended for patients having worse baseline conditions. Factors associated with increased involuntary treatment utilization were female sex, lower age, psychiatric comorbidities, more severe disease with lower weight at admission and a longer course.
Concerning short term outcomes, the involuntary treatment can be life saving and half of these patients accept the treatment in 2 weeks time. Studies show that the involuntary treatment did not have a significant negative impact in the doctor-patient therapeutic relation. In terms of long term outcomes, patients treated involuntarily had similar outcomes to those treated voluntarily, having better outcomes in some domains, including menstruation, number of admissions and functionality.
Conclusions: The denial of the illness and lack of insight in AN raise practical and ethical questions relating to the autonomy of the patient and the responsibility of the family and health care practitioners. The involuntary treatment of eating disorders is a complex area and further research including quantitative and qualitative studies is needed.

Subjective well-being in individuals with obsessive compulsive disorder: an exploratory study

R. B. Radins[1], J. V. B. Ferrão[3]*, J. P. B. Tomé[2,4], C. T. Reppold[1] and Y. A. Ferrão[1]

[1]PPGCS; [2]Psychiatry, UFCSPA; [3]Medicine, PUCRS and [4]Autism Treatment Reference Center, Porto Alegre City Hall, Porto Alegre, Brazil
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.702

Introduction: Subjective well-being (SWB), defined as the way people think and feel about their lives, is often used to evaluate happiness. Separated into three components—positive affect, negative affect, and life satisfaction—SWB has been indirectly related to psychiatric symptoms and disorders. However, the relationship between SWB and obsessive-compulsive disorder (OCD) remains relatively unknown.
Objectives: To determine whether SWB components correlate with the clinical features of OCD.
Methods: This was a cross-sectional study evaluating 68 individuals with OCD. Sociodemographic data were collected, treatment histories were taken, and validated instruments were applied (Y-BOCS, Dimensional Y-BOCS, USP-Sensory Phenomena Scale, BDI-II, BAI, Positive and Negative Affect Schedule (PANAS), and Satisfaction with Life Scale (SWLS)).
Results: All three SWB components showed inverse correlations with the severity of depressive/anxiety symptoms and total OCD symptom scores. Life satisfaction and positive affect showed inverse

correlations with suicidality. Life satisfaction and negative affect showed inverse correlations with the hoarding and contamination/cleaning OCD dimensions, respectively. No SWB aspect correlated with any other OCD dimension.
Conclusions: Some OCD-specific factors appear to correlate with SWB. However, it seems that the effect size is greatest for depressive symptoms, which suggests that depression mediates the relationship between OCD and SWB. Studies with larger samples and control groups are needed to confirm our findings.

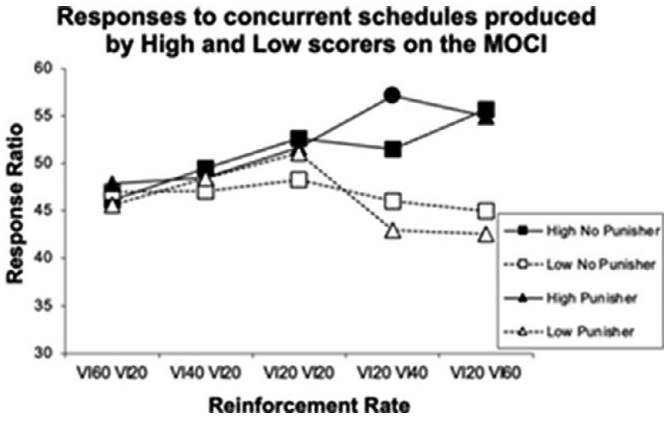
EPP431

The application of Matching Law in exploring obsessive-compulsive behaviour: A case-control study

A. Hassoulas[1]*, P. Reed[2] and L. McHugh[3]
[1]School of Medicine, Cardiff University, Cardiff; [2]Swansea University, Swansea, United Kingdom and [3]University College Dublin, Dublin, Ireland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.703

Introduction: The rigid maintenance of an acquired response in participants with obsessive-compulsive (OC) traits has been widely reported in the literature (e.g., Hassoulas et al., 2014; 2017; 2024). As such, demonstrating flexibility in responding to concurrently presenting stimuli with differing rates of reinforcement has also been shown to be difficult for those diagnosed with OCD (e.g., Clayton et al,, 1999). Matching Law proposes a quantifiable description of behaviour when consequences to responding under two concurrently presented schedules of reinforcement differ. The application of a matching procedure, whereby participants exhibiting OC traits are presented with concurrent schedules of reinforcement, would highlight this difficulty in distinguishing between stimuli that provide different rates of reinforcement. That is, the competing sources of reinforcement would relate to the concurrent stimuli that individuals with OCD have been shown to have trouble attending to separately.
Objectives: Sensitivity to concurrent schedules has not been previously investigated in the context of OCD. As such, two experiments were designed to measure matching behaviour between groups of participants with and without OC traits.
Methods: A total of 60 participants (33 females, 27 male) were recruited to take part in the two studies. The Maudsley Obsessive-Compulsive Inventory (MOCI) was used to screen for the presence of OC traits. Concurrent variable intervals (VI) were presented over ten trials, with an aversive auditory stimulus serving as a punisher superimposed during every second trial. During the first experiment, VI 20-second schedules were concurrently presented with VI 40-second and VI 60-second schedules. The ratio between concurrent schedules was widened during the second experiment; with VI 20-second schedules presented alongside VI 100-second and VI 180-second schedules.
Results: A significant interaction of trial with OC traits was revealed when the punisher was presented in experiment 1, $F(4,68)=2.68$, $p < 0.05$, but not in experiment 2 ($p>0.05$). The findings suggest that the presence of an auditory punisher facilitates schedule-sensitive responding in participants with OC traits, but that schedule-sensitivity is lost when intervals between concurrent schedules are widened. Figures 1 and 2 display response ratios for both high and low scoring groups during experiments 1 and 2 respectively.
Image 1:



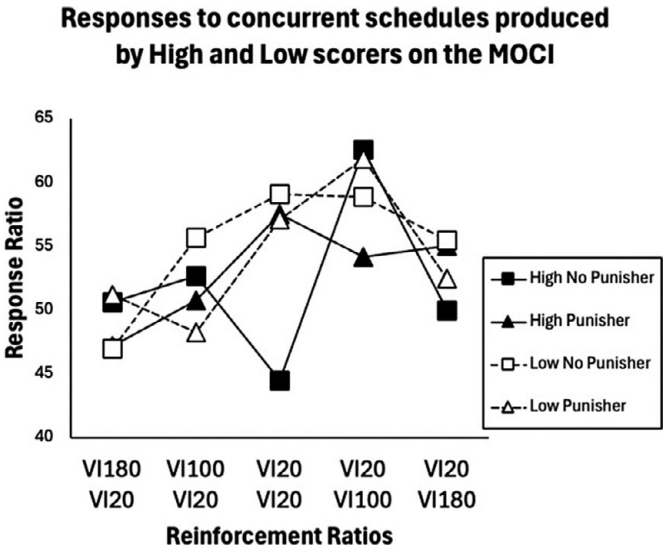


Image 2:

Conclusions: The widening of the schedule ratios in the second experiment disrupted sensitivity to the schedule contingencies for the OC group. Greater flexibility in responding within this group can therefore be facilitated by considering specific parameters and rates of reinforcement.

Obsessive-Compulsive Disorder Following Sydenham Chorea: A Case Report

M. O. Pires[1]*, H. J. Gomes[2] and J. Nunes[1]

[1]Unidade Local de Saúde da Guarda, Guarda and [2]Unidade Local de Saúde do Nordeste, Bragança, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.704

Introduction: Sydenham chorea (SC) is the most common form of autoimmune chorea and is one of the major clinical manifestations of acute rheumatic fever. Although related to group A streptococcal infection, its pathogenesis is not fully understood, and neither is its contribution to the development of Obsessive-Compulsive Disorder (OCD), with hypotheses like autoimmune mechanisms and neuroinflammation being probable. The prevalence of OCD in SC patients is higher than in the general population, with one study reporting obsessive-compulsive symptoms in 24% of SC patients (Moreira *et al.* Parkinsonism Relat Disord 2014;20(2):233-236). Psychiatric symptoms often fluctuate with motor symptoms, but their prognosis is poorly understood.
Objectives: To describe a case of a patient who developed OCD symptoms after SC.
Methods: We report a case of OCD that followed the development of chorea, and we perform a non-systematic review of the literature.
Results: A 34-year-old woman is referred to a Liaison Psychiatry consultation due to cognitive anxiety related to her non-psychiatric history. The patient, with no previous psychiatric history, has a personal history of rheumatic fever (9 years ago) and SC previously evaluated by Neurology consultation where brain magnetic resonance imaging and head computed tomography changes were ruled out, as well as the genetic panel for Huntington disease. No relevant family history. Medicated with sertraline 100mg daily, alprazolam 1mg three times a day, clopidogrel 75mg daily, propranolol 10mg three times a day and atorvastatin 10mg daily. Upon the evaluation, the patient referenced anxiety related to a programmed cardiac surgery and initial and intermediate insomnia. When questioned, the patient reported, after the development of chorea, obsessive ideas and verification rituals/compulsions. These symptoms are time-consuming and cause clinically significant distress and impairment in her work and social functioning. The patient was started on risperidone 0.5mg daily due to its high-potency dopamine D2 receptor blockage that could benefit the chorea and its proprieties in obsessive-compulsive disorder. Six months later, the patient presented an improvement in motor symptoms and a satisfactory Y-BOCS reduction response to the initiated plan.
Conclusions: This case underscores the unusual but significant association between SC and the development of obsessive-compulsive symptoms, contributing to the growing body of evidence that autoimmune processes may underlie neuropsychiatric manifestations such as OCD. The patient's favorable response to risperidone, a dopamine receptor antagonist, emphasizes the role of dopaminergic dysregulation in both SC and OCD. This case underscores the need for a multidisciplinary approach, including neurology and psychiatry, to manage SC's neuropsychiatric effects. Further research is needed to clarify how SC relates to OCD and to improve treatment strategies.

Orthorexia Nervosa, Eating Disorders, and OCD: A Literature Review and Diagnostic Challenges

M. A. Rodrigues[1]*, F. M. Amorim[1], M. H. R. Delgado[1] and L. A. Lemes[1]

[1]Universidade Anhembi Morumbi, São Paulo, Brazil
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.705

Introduction: Orthorexia Nervosa (ON) is characterized by an obsessive focus on healthy eating, leading to extreme restrictions and negative impacts on mental and social health. ON shares traits with eating disorders (EDs) and obsessive-compulsive disorder (OCD), but its diagnostic status remains unclear. Recent studies suggest ON may be linked to personality traits like perfectionism, common in both EDs and OCD (3,5). The COVID-19 pandemic has exacerbated these issues, stressing the need for better understanding of ON and its overlaps with other disorders (6).
Objectives: This study reviews literature from the past seven years to explore the connections between ON, EDs, and OCD. It examines ON as a possible distinct diagnosis, focusing on the role of personality traits like perfectionism and evaluates the clinical implications and treatment needs, considering cultural and contextual factors.
Methods: A systematic review was conducted using PubMed, PsycINFO, and Scopus, covering studies from 2017 to 2023. The studies included clinical and non-clinical samples, focusing on psychopathological features and personality traits linked to ON, EDs, and OCD (1-2). The review analyzed diagnostic criteria, prevalence, personality trait correlations, and the impact of contextual factors like the COVID-19 pandemic.
Results: ON has a complex relationship with EDs and OCD. In ED patients, especially those with anorexia nervosa (AN) and bulimia nervosa (BN), orthorexic behaviors were more prevalent, suggesting ON might be a subtype of EDs rather than a separate condition. ON scores in ED patients decreased after targeted treatment, supporting this connection (1). Personality studies showed that orthorexic individuals often display perfectionism, particularly concerns about mistakes and unrealistic standards. These traits are transdiagnostic, affecting ON, EDs, and OCD (2-3). ON was also linked to specific personality profiles, such as paranoid and narcissistic traits, which worsen symptoms and complicate treatment (2). ON symptoms were strongly correlated with anxiety, depression, and ED and OCD symptoms, indicating shared psychopathological mechanisms (5). The ego-syntonic nature of ON, where behaviors are seen as normal, may lead to underdiagnosis and reduced treatment-seeking (5). The COVID-19 pandemic further exacerbated orthorexic behaviors, highlighting the need for tailored clinical interventions for at-risk individuals (6).
Conclusions: ON should be viewed within the ED spectrum, with significant overlaps with OCD and influence from traits like perfectionism. Cultural and definitional differences complicate its classification as a distinct disorder. The COVID-19 pandemic has highlighted the clinical importance of ON and the need for effective prevention and treatment strategies. Future research should aim to develop standardized diagnostic criteria and explore personality traits to improve ON diagnosis and treatment.

Efficacy and Safety of Evenamide, a glutamate modulator: Results from a Phase 2/3, international, randomized, double-blind, placebo-controlled add-on trial

R. Anand[1]*, A. Turolla[2], G. Chinellato[2], R. Giuliani[2], F. Sansi[2] and R. Hartman[3]

[1]R&D, APC, St Moritz, Switzerland; [2]R&D, Newron Pharmaceuticals SpA, Milan, Italy and [3]R&D, NeurWrite LLC, Morristown, United States

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.706

Introduction: Treatment of schizophrenia remains a challenge despite the development of numerous antipsychotics (AP) (Pompili et al CNS NDDT 2017; 16 870-884). The various strategies to address patients' unmet needs, such as AP polypharmacy or switching AP, do not seem to provide adequate benefit. A reason for this may reside in the similarity of mechanisms of action of most APs. However, the monoaminergic systems targeted by these drugs are not always disrupted in schizophrenia, as it is widely accepted that patients who fail to respond to AP have glutamatergic, but not dopaminergic dysfunctions (Moghaddam et al NPP 2012; 37 4-15). Evenamide normalizes excessive glutamate release without affecting its basal levels, and it does not interact with >150 CNS targets. It has been shown to be effective in animal models of psychosis as monotherapy and add-on to AP. Previous trials indicate that evenamide benefits patients with schizophrenia with inadequate response and have shown clinically important benefits lasting up to 1-year in TRS (Anand et al IJNPP 2023; 26 523-528).
Objectives: Study 008A, a phase 2/3 international, randomized, double-blind, placebo-controlled, 4-week trial, assessed the efficacy and safety of evenamide 30 mg *bid* as add-on in patients poorly responding to an SGA.
Methods: Outpatients with a diagnosis of schizophrenia, still symptomatic (PANSS 70-85; CGI-S 4-6) despite treatment with an SGA at a therapeutic dose (confirmed through plasma levels) for an adequate period, were enrolled. Efficacy was assessed on the PANSS, CGI-S, and LOF through the comparison of changes from baseline to Day 29 between evenamide and placebo groups using a MMRM analysis. Moreover, the proportion of patients reaching a clinically important improvement on the PANSS and CGI-C were compared between groups using a logistic regression model (chi-square test). Safety measures comprised: TEAEs, vital signs, labs, ECG/EEG, seizure checklist, physical/neurological/eye examinations, C-SSRS, ESRS-A, CDSS.
Results: 291 patients were randomized in the study in 11 countries (EU, Asia and LATAM), and 280 completed the study. The low attrition rate (<4%), and proportion of patients with TEAEs (~25% in both groups) indicate that evenamide was well tolerated. A statistically significant greater improvement was found on the PANSS total score and on the CGI-S in the evenamide compared to the placebo group. Furthermore, a significantly higher proportion of patients treated with evenamide, compared to those receiving placebo, experienced clinically meaningful benefit measured on the PANSS (≥20% improvement) and CGI-C (at least much improved).
Conclusions: This is the first randomized, placebo-controlled trial to demonstrate the clinical benefit of adding a NCE modulating glutamate in patients with schizophrenia who did not experience adequate response from treatment with a SGA.

doi: 10.1192/j.eurpsy.2025.707

Introduction: Adverse childhood events have been associated with immune aberrations. Herpes simplex virus 1 (HSV1), a neurotropic pathogen, establishes persistent infection after primary exposure. Elevated HSV1 immunoglobulin (IgG) levels have been found in HSV1-infected patients with severe mental illness (SMI), which likely reflects immune dysregulation.
Objectives: We assessed childhood maltreatment and HSV1 IgG concentrations in adult patients with SMI and healthy controls. We hypothesized that maltreatment would be associated with elevated HSV1 IgG concentrations reflecting a failure in immune competence, and that such a putative association would be stronger in or even restricted to patients.
Methods: We included 448 adult patients with SMI (mean age=31 years, 48% women, 46% HSV1 seropositive), i.e., 259 patients with schizophrenia spectrum and 189 patients with bipolar disorders, and 271 adult healthy controls (mean age=32, 41% women, 46% HSV1 seropositive). We assessed childhood maltreatment with the Childhood Trauma Questionnaire (CTQ), a 28-item retrospective self-report scale. We evaluated circulatory HSV1 IgG concentrations, expressed as continuous and dichotomous measures. In our main analyses, we applied sex- and age-adjusted multiple regressions on HSV1 IgG concentrations.
Results: In patients with SMI ($p=0.002$) but not in healthy controls ($p=0.203$), CTQ total score was associated with HSV1 IgG seropositivity. Among seropositive patients ($p<0.001$) but not healthy controls ($p=0.957$), CTQ total score was associated with increased HSV1 IgG concentrations. Post-hoc analysis among seropositive patients showed that the five subscale scores for physical ($p=0.002$), sexual ($p=0.019$) and emotional abuse ($p=0.002$), and physical

(p=0.012) and emotional neglect (p=0.016) were all associated with increased HSV1 IgG concentrations.
Conclusions: Among patients with SMI, childhood maltreatment is associated with an increased risk of HSV1 infection. Further, among HSV1-infected patients, maltreatment is associated with elevated HSV1 antibody concentrations which may reflect a link between childhood adverse experiences and an immune system dysregulation.

Am I sentenced to life-long use of antipsychotics? A qualitative analysis of Q&A data about stopping antipsychotics from the perspective of users and their relatives

S. Crutzen[1]*, J. van Os[2,3,4] and S. Castelein[1,5]

[1]Lentis Research, Lentis Psychiatric Institute, Groningen; [2]UMC Utrecht Brain Centre, University Medical Centre Utrecht, Utrecht; [3]Department of Psychiatry and Neuropsychology, Maastricht University Medical Centre, Maastricht, Netherlands; [4]Institute of Psychiatry, King's College London, London, United Kingdom and [5]Department of Clinical Psychology and Experimental Psychopathology, University of Groningen, Groningen, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.708

Introduction: The majority of antipsychotic users at some point want to stop their antipsychotic medication and many do so without consulting their attending physician. So-called non-adherence to antipsychotics has been estimated to be as high as 60% and it has been identified as the most important predictor for relapse, resulting in a four times higher risk of relapse. When asking antipsychotic users, different reasons for wanting to stop are mentioned. These reasons include severe side effects, reduced functioning, experiencing no benefits and long-term physical health concerns. From the perspective of patients, wanting to stop can be considered an understandable and rational reaction given the burdens that antipsychotic use often imposes. Given the current uncertainties surrounding stopping antipsychotics, and given the patients' wish to be involved in treatment decisions and a move away from a paternalistic mental health care model, several shared decision initiatives have been formed to involve patients more in the decisions about stopping or reducing the dose of their antipsychotic. In order to support shared decision-making, insight is needed in which questions antipsychotic users have.
Objectives: The current study aims to gain insight in which questions antipsychotic users and their relatives have, and which factors influence stopping or reducing the dose of antipsychotics, by qualitatively analysing questions posted on an online expert Q&A.
Methods: Data were used from a Dutch existing publicly available anonymous expert Q&A. Questions about stopping or reducing the dose of antipsychotics were analysed using an inductive thematic approach. Questions antipsychotic users and their relatives had about this topic and factors that influences the process were identified.
Results: In total 194 out of 3000 screened questions were about stopping or reducing antipsychotic dose. The most common question was whether it was sensible to stop or reduce the dose. Questions focused on how fast to reduce the dose, what their minimum dose should be and where they could find support. Those that were phasing out their antipsychotic asked when withdrawal symptoms or side effects would subside. Motivations to stop were side effects, difficulties in assuming a normal life and social roles and experiencing no benefits. Barriers were lack of support and return of symptoms. Facilitators were support from others and experiencing a relief from side effects and/or symptoms. Finally, questions were asked about activities that might support discontinuation.
Conclusions: Antipsychotic users continue to be left with many questions about stopping or reducing the dose of antipsychotics. These questions reveal attitudes, preferences and concerns regarding antipsychotic treatment that are important to address when discussing antipsychotic treatment.

Effectiveness of a community-based, multicomponent and case managed treatment for patients with severe schizophrenia

J. J. Fernández-Miranda[1]*, S. Díaz-Fernández[1] and F. López-Muñoz[2]

[1]AGCSM V- Hospital de Cabueñes, SESPA, Gijón and [2]Health Sciencies, Universidad Camilo J. Cela, Madrid, Spain
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.709

Introduction: Case management is a model of community intervention in people with severe mental illness.
Objectives: To explore the treatment adherence and effectiveness of patients with severe schizophrenia undergoing treatment in a community-based, case management program (CMP) with an integrated pharmacological and psychosocial approach compared to the standard treatment.
Methods: An observational, longitudinal study was conducted with a ten-year follow-up of patients with severe schizophrenia (CGI-S ≥ 5) treated in mental health units (MHUs) or on a CMP (N = 688). All causes of treatment discontinuation, psychiatric hospital admissions, suicide attempts, and antipsychotic (AP) medications were recorded. Clinical severity was assessed with the CGI-S.
Results: Adherence to the CMP was higher than to the standard treatment ($p < 0.001$). There were fewer hospital admissions and suicide attempts on the CMP than in standard care ($p < 0.001$). Clinical severity decreased more in the CMP than in MHUs ($p < 0.005$). Long-acting injectable (LAI) AP medication was more closely related to these outcomes than oral APs ($p < 0.001$) in both settings, but especially on the CMP.

Treatment clinical outcomes after 10-year follow-up

N = 688	Mental Health Units (N = 344)	Case Management Program (N = 344)	χ^2; P value
Treatment discontinuation (N (%))	150 (43.6)	42 (12.1)	26.16; < 0.0001
CGI-S (Av (SD))	3.9 (1.1)	3.1 (0.9)	7.63; < 0.005
Hospitalization (N (%))	160 (46.5)	60 (17.4)	10.54; < 0.0001
Hospitalization (Av (SD))	3.2 (3.4)	0.9 (0.3)	13.23; < 0.0001
Involuntary hospital. (N (%))	34 (9.9)	5 (1.4)	28.01; < 0.0001
Involuntary hospital. (Av (SD))	0.5 (0.3)	0.01 (0.2)	21.31; < 0.0001
Suicide attempt (N (%))	85 (24.7)	20 (5.8)	10.54; < 0.0001
Num. suicide attempts (Av (SD))	0.3 (0.1)	0.07 (0.02)	11.32; < 0.0001

N: number of patients %: percentage of patients Av: average SD: standard deviation
: basal (at beginning of program) **: standard treatment *: Program treatment*

Conclusions: The treatment of patients with severe schizophrenia in a multicomponent, case-managed program recorded higher compliance and effectiveness compared to standard care. Treatment with LAI antipsychotics was linked to these outcomes. A combination of case management, psychosocial approach, and LAI AP medication contributed more to the achievement of clinical goals in these patients than the standard treatment and oral APs.

Reconsidering evidence for psychedelic-induced psychosis: An overview of reviews, a systematic review, and meta-analysis of human studies

M. Sabé[1,2]

[1]Adult Psychiatry, Geneva University Hospitals and [2]Faculty of Medicine, University of Geneva, Geneva, Switzerland
doi: 10.1192/j.eurpsy.2025.710

Introduction: Persons with schizophrenia are currently excluded from psychedelic-assisted therapy due to concerns about psychedelic-induced acute or persistent psychotic symptoms. However, meta-analytic evidence of the precise risk for psychedelic-induced de novo and exacerbation of psychosis in people with pre-existing psychotic disorders is lacking.
Objectives: We conducted an overview of reviews, systematic review, and meta-analysis to examine the incidence of psychedelic-induced psychosis and the exacerbation of psychotic symptoms in schizophrenia.
Methods: Our pre-registered protocol (CRD42023399591) covered: LSD, psilocybin, mescaline, DMT, and MDMA. Embase, PubMed, PsyARTICLES, PsyINFO, and trial registries were searched from inception until 11/2023.
Results: The incidence of psychedelic-induced psychosis was computed using a random-effects model, and standardized assessments of study quality was performed. We retained 131 publications: 14 systematic reviews, 20 reviews, 35 randomized-controlled trials (RCTs), 10 case-control studies, 30 uncontrolled trials (UCT), and 22 cohort studies with overall low study quality. The meta-analysis included nine studies. Incidence of psychedelic-induced psychosis was 0.002% (95%CI 0-0.006, I^2=0%, N=123,800; n=2) in population studies; 0.2% (95%CI 0.1-0.3, I^2=0%, N=6,535; n=6) in UCT, and 0.6% (95%CI 0.2-1.8, I^2=0%, N=563; n=3) in RCTs excluding individuals with a history of psychotic symptoms. In UCT including patients with schizophrenia, 3.8% (95%CI 1.6-8.9, I^2=0%, N=133; n=2) developed long-lasting psychotic symptoms. In cohort studies, 13.1% (95%CI 9.4-17.9, I^2=24%, N=353; n=3) of those with psychedelic-induced psychosis developed schizophrenia. Sensitivity analyses confirmed the main findings. The incidence for psychedelic-induced psychosis is low but slightly higher in studies including patients with schizophrenia. The risk of transition to schizophrenia after psychedelic-induced psychosis is considerable.
Conclusions: In summary, the reviewed evidence suggests that schizophrenia might not be a definite exclusion criterion for clinical trials exploring safety and efficacy of psychedelics for treatment-resistant depression and negative symptoms. However, given the low quality and limited number of studies, more high-quality research is needed, and a conservative approach is recommended until further data is available.

Do Patients with Psychosis See Their Symptoms the Same Way Clinicians Do?

P. Seif[1]*, G. Shashidhar[1], T. Khan[1] and M. Keshavan[1]

[1]Psychiatry and Mental Health, Beth Israel Deaconess Medical Center, Boston, United States
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.711

Introduction: Psychosis includes positive (e.g., hallucinations) and negative symptoms (e.g., anhedonia), with tools like the PANSS traditionally used for evaluation. Although clinician-administered scales are considered the gold standard, patient self-reports provide critical insights into subjective experiences.
Objectives: This study explores the discrepancies between patient-reported and clinician-assessed symptoms, aiming to improve psychosis diagnosis and treatment.
Methods: Part of the BSNIP project, this study analyzed data from 159 participants (primarily male, average age 34.33) at the Boston site. Diagnoses were based on SCID, with most participants having schizophrenia, schizoaffective disorder, or bipolar disorder with psychotic features. The DSM-5 Level 1 Cross-Cutting Symptom Measure assessed psychiatric domains, including depression, anxiety, suicidal ideation, and psychosis, and was compared with clinician-reported assessments of the same symptoms.

Results: Clinicians generally reported higher anxiety levels than patients with SZ (Z = -2.462, p = 0.014), while no significant differences were observed for the bipolar disorder (BP) and schizoaffective disorder (SAD) groups. Regarding suicidal ideation, patients typically reported higher levels than clinicians, particularly in the SZ group (Z = -3.507, p < 0.001) and the SAD group (Z = -2.007, p = 0.045). Similarly, patients in the BP (Z = -2.822, p = 0.005) and SAD (Z = -2.145, p = 0.032) groups reported more hallucinations compared to clinician assessments, while clinicians reported higher levels of hallucinations in the SZ group (Z = -3.451, p = 0.001). In terms of delusions, clinicians generally reported higher levels than patients in the SZ group (Z = -2.925, p = 0.003). Additionally, neither insight (PANSS_G12) nor cognitive function (BACS Composite) significantly impacted the discrepancies between patient and clinician reports of suicidal ideation, hallucinations, or delusions.
Conclusions: The study highlights significant discrepancies in the reporting of anxiety, suicidal ideation, hallucinations, and delusions, especially in schizophrenia, where patients tend to underreport anxiety and psychotic symptoms but report higher suicidal ideation. Our findings point to the value of obtaining both patient and clinician assessments when evaluating psychosis.

Neurological Soft Signs and Thyroid Hormones in Schizophrenia

E. M. Tsapakis[1]*, M. Treiber[2,3], S. Athanasiou[1], K. Chovardas[1], T. Kyziridis[1] and K. N. Fountoulakis[1]

[1]3rd Department of Psychiatry, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]Department of Psychiatry and Psychotherapy, Medical Univeristy of Vienna and [3]Comprehensive Center for Clinical Neurosciences and Mental Health (C3NMH), Medical University of Vienna, Vienna, Austria
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.712

Introduction: Neurological soft signs (NSS) are subtle sensory and motor deficits linked to neurodevelopmental disorders, schizophrenia, and thyroid disorders (TH). TH are essential for neurodevelopment and the modulation of the proinflammatory response. Indeed, a growing body of evidence suggests that thyroid function is altered in individuals with schizophrenia spectrum disorders (SSD).
Objectives: We aimed to evaluate the relationship between TH, NSS, and psychopathology in individuals with schizophrenia.
Methods: Opportunistic recruitment took place at the 3rd Department of Psychiatry at AHEPA University General Hospital of Thessaloniki, Greece. Inclusion criteria were an SDD diagnosis and age above 18 or below 65 years. Patients were excluded if they had a history of neurological or other somatic disorder, a history of substance abuse, an IQ estimate <70, and if they were pregnant, or on treatment with glucocorticoids and/or thyroxin. Clinical symptomatology was assessed using the Positive and Negative Syndrome Scale (PANSS), and NSS were assessed using the Neurological Evaluation Scale (NES; Greek version). Blood samples were drawn after an overnight fast to measure serum levels of TSH, fT4, and fT3. We used the t-test to compare differences between sex and the Pearson correlation to test for correlations between PANSS scores, NES scores, and TH (R statistical software version 4.3.2).
Results: A total of 73 patients (31 female) with SSD were included [mean age 41.2 (SD 11.6) years]. TSH and fT4 levels were significantly higher in females, p<0.0005 and p=0.020, respectively. fT3, but not fT4 or TSH, was negatively correlated with age (r=-0.479, p<0.001). A negative correlation between NES total score and fT4 (r=-0.416, p=0.014) was only found in males. Serum fT3 levels exhibited no significant correlation with NES scores but the PANSS negative subscore was negatively associated with fT3 (r=-0.471, p<0.001).
Conclusions: Our study suggests that TSH and fT4 abnormalities are more prevalent in females with SSDs. Moreover, it appears that with increasing age, the likelihood of hypothyroidism increases. Interestingly, in individuals with SSDs, lower fT4 levels predicted NSS severity but only in males, and lower fT3 levels predicted an increase in negative symptoms. Hypothyroidism has been reported to cause damage to the central nervous system and has been associated with increased apoptosis and altered expression of cerebellar neurons leading to impairment in motor function. In this sense, restoring fT3 and fT4 levels might have a positive effect on negative symptoms and NSS severity (in males), respectively. However, antipsychotic medication may affect TH levels in SSDs. Thus, future studies should examine a larger sample of drug-naïve individuals with SSDs, followed-up longitudinally in time to infer causality.

Functional Outcomes Over 5 Years in First-Episode Schizophrenia Patients: Key Insights from a Longitudinal Cohort Study in Turkey

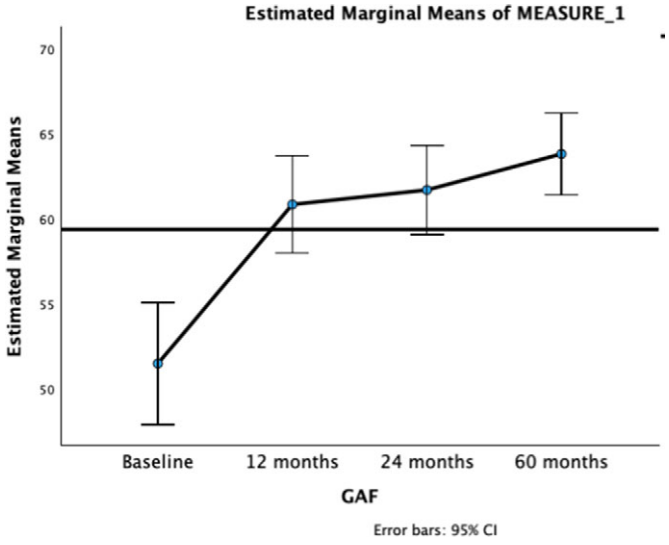
E. Ince Guliyev[1], S. N. Karabulut[1], M. Ceylan[1], C. C. Türkoğlu[1]*, C. Horasan[1] and A. Üçok[1]

[1]Psychiatry, Istanbul University Faculty of Medicine, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.713

Introduction: First-episode schizophrenia (FES) is a critical period where early intervention can influence long-term outcomes. Tracking functional changes and finding their correlates are essential for understanding the disease process.
Objectives: This study aims to evaluate the progression of functional outcomes over a five-year follow-up in FES patients and to examine the clinical correlates of functioning in the fifth year.
Methods: This cohort study included 197 FES patients admitted to the Istanbul Faculty of Medicine Department of Psychiatry Psychotic Disorders Research Program. Global Assessment of Functioning (GAF), Brief Psychiatric Rating Scale(BPRS), and Scale for the Assessment of Negative Symptoms(SANS) scores were recorded, and a comprehensive neuropsychological battery was applied at baseline. FES patients were evaluated regularly with the same clinical scales and GAF scores. The baseline clinical and cognitive parameters and clinical parameters at 1st, 2nd and 5th years were compared with GAF scores over the years. A repeated measures ANOVA was conducted to examine the effect of time on GAF scores over a 5-year follow-up, as well as the effects of gender and education. SPSSv29 was used to conduct all statistical analyses, and significance levels were set at p<0.05.
Results: Seventy-seven FES patients had a follow-up duration of at least five years. Of these, 36.4% (n=28) were female, and the mean

age was 22.18±6.09 years. The mean follow-up duration was 133.09 ±56.94 months. The mean GAF scores were 51.44±12.71 at baseline, 60.00±9.48 at the end of the first year, 62.14±9.04 at the end of the second year, and 62.89±8.34 at the end of the fifth year. There was a significant effect of time on GAF scores, $F(2.56, 182.8) = 26.43$, $p < 0.001$, partial $\eta^2 = 0.29$, with scores improving significantly from baseline to year 1 ($p<0.001$), and further improving by year 5 ($p=0.034$). There was also a significant effect of time*gender interaction on GAF scores, $F(2.56,40.9) = 6.17$, $p=0.001$, although there is no direct effect of gender ($p=0.740$). No direct effect of education or time*education interaction was found (p values >0.05). Additionally, baseline RAVLT-5 (r=0.725; p0.001), Stroop Time difference (r=-0.718; p0.001), WCST correct answers (r=0.644; r=0.003), category completed (r=0.630; p=0.004), and SANS scores (r=-0.427; p=0.42) significantly correlated with GAF in the 5th year. Among the CTQ subscores, physical abuse was significantly correlated with GAF in the 5th year (r=-0.415; p=0.009).

Image 1:



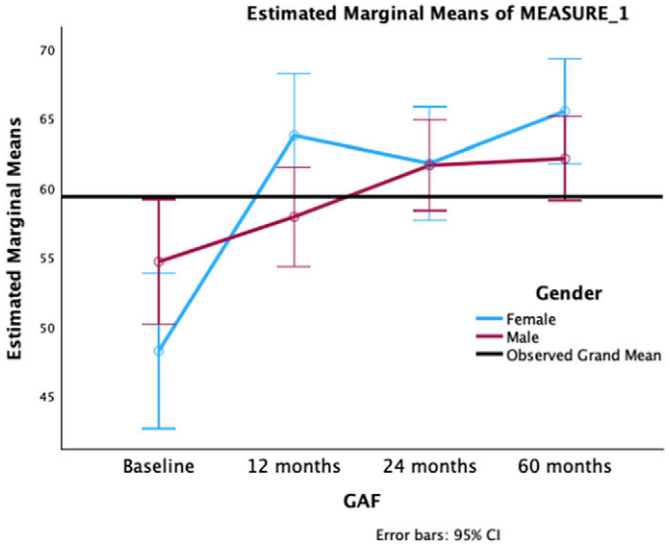


Image 2:

Conclusions: GAF scores improved significantly over the 5-year follow-up in FES patients, with notable improvements occurring in the first year. Baseline cognitive performance, negative symptoms, and childhood trauma were found to be significant correlates of functioning, highlighting potential targets for early intervention.

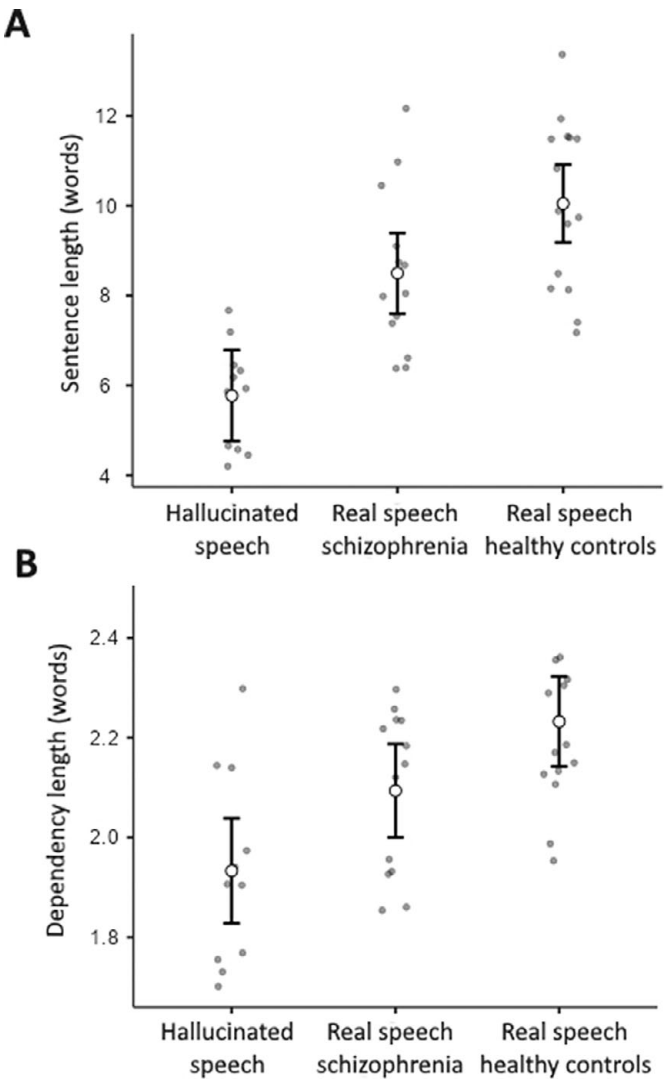
Voices in patients with schizophrenia talk in short, simple sentences

P. Del Olmo[1,*], P. Fuentes-Claramonte[1,2], J. Soler-Vidal[1,2], F. Neuhaus[1,3], L. López-Araquistain[1,4], L. Barbosa[1], P. Salgado-Pineda[1,2], S. Sarró[1,2], R. Salvador[1,2], J. Rosselló-Ximenes[5], P. J. McKenna[1,2] and E. Pomarol-Clotet[1,2]

[1]FIDMAG Germanes Hospitalàries Research Foundation; [2]CIBERSAM, ISCIII, Barcelona, Spain; [3]Maastricht University, Maastrich, Netherlands; [4]Hospital Sant Rafael and [5]Departament de Filologia Catalana i Lingüística General, Universitat de Barcelona, Barcelona, Spain

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.714



Introduction: Auditory verbal hallucinations (AVH) are prevalent in schizophrenia and are often distressing. However, relatively little is known about their linguistic structure, although a number of authors have commented that they tend take the form of short, syntactically simple sentences (Tovar *et al* Schizophr Res 2019; 206 111-117; Corona-Hernández *et al* Schizophr Res 2022; 241 210-217). It has been suggested that these features may be related to the high frequency with which AVH feature insults and commands (which are normally short and simple).

Objectives: We aimed to quantify sentence length and complexity of AVH in schizophrenia patients, and to examine how far length reductions were attributable to presence of insults and commands. We also examined the same variables in real speech from patients with schizophrenia and healthy controls.

Methods: We transcribed verbatim AVH from 11 patients with very frequent AVH following a previously used protocol (Fuentes-Claramonte *et al* Sci Rep 2021; 23 18890). Mean sentence length and mean dependency distance (a measure of syntactic complexity) were calculated using the *udpipe* package in R. Insults and commands were also coded. For comparison, (real) speech samples were collected and transcribed from patients with schizophrenia (N=14) and healthy controls (N=15). All groups were matched for age, sex and estimated premorbid IQ.

Results: We found that AVH sentences were on average significantly shorter ($t_{(37)}= -6.51$, $p < 0.001$; see Fig. 1A) and syntactically simpler ($t_{(37)}= -4.37$, $p < 0.001$; see Fig. 1B) than in the (real) speech of healthy controls. AVH sentences were also shorter (Fig. 1A) and simpler (Fig. 1B) than the speech of schizophrenia patients, although the latter comparison only approached significance ($t_{(37)}= -4.09$, $p < 0.001$ and $t_{(37)}= -2.31$, $p = .08$, respectively). After insults and commands were removed from the analysis, AVH sentences were still shorter ($t_{(37)}= -6.09$, $p < 0.001$) and simpler ($t_{(37)}= -3.89$, $p < 0.001$) than those in the speech of controls, and shorter ($t_{(37)}= -3.68$, $p < 0.01$) than those in the speech of patients, but not simpler ($t_{(37)}= -1.86$, $p = 0.213$).

Image 1:

Conclusions: From our data AVH mainly (though not exclusively) take the form of short and simple sentences. These features are not explained by presence of insults and commands.

Clozapine: prescribing practices in French psychiatric hospitals, multicenter survey on a given day

D. Espeillac[1], E. Queuille[2,3] and R. Klein[1]*

[1]Haute-Garonne, Ferrepsy, Toulouse; [2]Gironde, CH Charles Perrens, Bordeaux and [3]Nord, Association du réseau PIC, Armentieres, France
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.715

Introduction: Efficacy of clozapine has now been proven for all symptoms of resistant schizophrenia. Yet it remains underused in view of the prevalence of drug resistance and unevenly prescribed worldwide despite a general trend towards increasing prescribing (Bachmann et al. Acta Psychiatr Scand 2017; 1-15). Data on hospital clozapine prescribing in France are older and single-center (Mercier et al. L'Encéphale 2009; 35, 321-329). Collaboration between a national multi-professional network (pharmacist, general practitioner, psychiatrist) working in various public or private mental health establishments (the PIC network) and a regional psychiatric research federation (FERREPSY Occitanie) has enabled a broad and up-to-date study of practices.

Objectives: To assess the prevalence of clozapine prescribing among patients hospitalised in full-time psychiatry on a given day. To assess the prevalence of clozapine prescribing in inpatients with a diagnosis of non-organic psychotic disorder (ICD 10: F20-F29). To study the characteristics of patients treated, prescribing methods and clinical monitoring.

Methods: A cross-sectional observational study was carried out in December 2023 with teams from establishments belonging to the PIC and/or FERREPSY network who had volunteered.

Results: 30 centers took part in the study, with a total of 795 patients included. The average age was 44.1 years (66% men and 34% women). 14.05% of hospitalised patients were receiving clozapine treatment on the day of the survey. 25.07% of patients with a diagnosis of non-organic psychotic disorder were receiving clozapine treatment. 26.83% of clozapine prescriptions were off-label, mainly for patients with mood disorders. 91.94% of patients had had their blood pressure measured in the quarter preceding the survey, and 91.82% had been weighed. Conversely, only 31.94% had their umbilical circumference measured.

Conclusions: This study found that the prevalence of prescribing among patients with non-organic psychotic disorders in the hospital was higher than expected, according to European data on clozapine prescription Further data on outpatient use are still required.

Sex-related differences in long-term tolerability of Risperidone ISM treatment in adult patients with schizophrenia

J. Martínez González[1]*, C. Sherifi[2], L. Anta Carabias[1], M. Almendros Gimenez[1], C. Salazar García[1] and C. U. Correll[3,4,5,6,7]

[1]Medical Department, Laboratorios Farmaceuticos ROVI S.A., Madrid, Spain; [2]Medical Affairs, ROVI Biotech Ltd., Croydon, United Kingdom; [3]Department of Psychiatry and Molecular Medicine, Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Hempstead, NY; [4]Department of Psychiatry Research, The Zucker Hillside Hospital, Glen Oaks, NY, United States; [5]Department of Child and Adolescent Psychiatry, Charité Universitätsmedizin Berlin, Berlin, Germany; [6]Center for Psychiatric Neuroscience, The Feinstein Institute for Medical Research, New Hyde Park, NY, United States and [7]German Center for Mental Health, Partner Site Berlin, DZPG, Berlin, Germany
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.716

Introduction: Sex-related differences in antipsychotic treatment exist with some specific differences having been reported with risperidone use. Women may respond better to antipsychotics than men, but also experience more side effects. In a randomised

controlled trial of 1460 participants, a significantly higher proportion of female than male study participants treated with risperidone reported greater rates of gynecomastia/galactorrhoea and incontinence/nocturia. There is a call to consider sex differences in mental health research [Galbally et al. CNS Drugs 2024; 38(7):559-570]. Risperidone ISM (Risp-ISM) is a monthly long-acting injectable (LAI) formulation of risperidone, recently authorised in Europe, USA and some other countries.

Objectives: To investigate the sex-related differences in the safety of Risp-ISM in patients with schizophrenia during the PRISMA-3 study.

Methods: A post-hoc analysis was performed on the PRISMA-3, 12-month open-label extension (OLE) study (NCT03870880) data [Filts et al. Schizophr Res. 2022; 239:83-91 [published correction in Schizophr Res. 2022; 246:258-259]].

Results: 215 patients received at least one dose of Risp-ISM. 84 (39%) were female. 66 (78.57%) females and 100 (76.33%) males experienced a treatment-emergent adverse event (TEAE). A lesser proportion of treatment-related (TR) TEAEs were experienced by females (F:45%; M:55%).

Overall, the most frequently reported (in ≥2% cases) TR-TEAEs are shown in Figure 1 and those leading discontinuation in Table 1. No cases of incontinence/nocturia were reported in either sex.

Image 1:

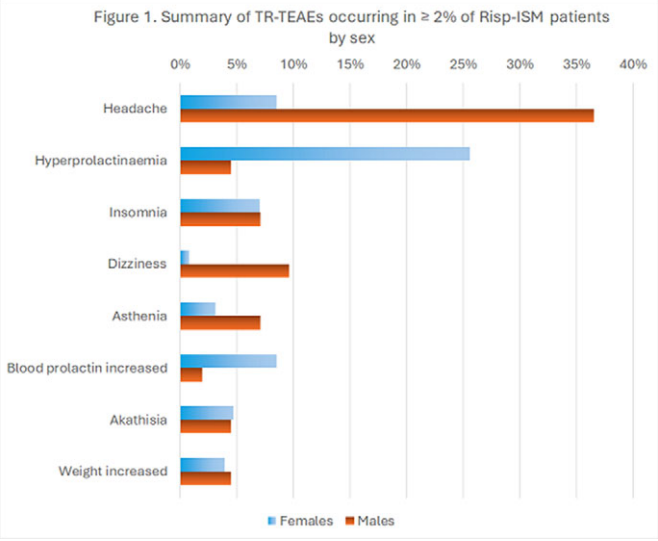

Image 2:

Table 1. Summary of treatment-related TEAEs leading to study drug discontinuation and their overall incidence by sex.

	Females		Males	
	Overall incidence n (%)	Incidence leading to discontinuation n (%)	Overall incidence n (%)	Incidence leading to discontinuation n (%)
Akathisia	6 (4.65)	0 (0)	7 (4.49)	1 (0.64)
Diabetes mellitus	1 (0.78)	1 (0.78)	0 (0)	0 (0)
Extrapyramidal disorder	4 (3.1)	1 (0.78)	0 (0)	0 (0)
Gynaecomastia	0 (0)	0 (0)	1 (0.64)	1 (0.64)
Hepatic steatosis	1 (0.78)[a]	1 (0.78)	0 (0)	0 (0)
Hepatocellular injury	1 (0.78)[a]	1 (0.78)	0 (0)	0 (0)
Libido decreased	1 (0.78)	0 (0)	2 (1.28)	1 (0.64)
Weight increased	5 (3.88)	1 (0.78)	7 (4.49)	0 (0)

[a] Both TR-TEAEs occurred in the same participant

Conclusions: Relating to the use of Risp-ISM, a lesser proportion of TR-TEAEs were experienced by females than males (45% vs 55%). Male participants were more likely to report dizziness and headache. Females were more likely to report raised blood prolactin and hyperprolactinaemia. This is in line with the findings in a large study which reported a significantly greater increase in prolactin levels among female participants [Galbally et al. CNS Drugs 2024; 38(7):559-570]. Very few participants discontinued Risp-ISM following a TR-TEAE (7/215 [3.3%]) during this 12-month extension phase [Filts et al. Schizophr Res. 2022; 239:83-91. [published correction in Schizophr Res. 2022; 246:258-259]].

Copenhagen prodromal study III : Long term stability of self-disorders

S. Ørsted[1]*, M. G. Henriksen[2] and J. Nordgaard[2]

[1]Mental Health Center Amager and [2]Psychiatry Region Zealand, University of Copenhagen, Copenhagen, Denmark

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.717

Introduction: Detailed knowledge on prognostic predictors and illness trajectories of many mental disorders, especially schizophrenia spectrum disorders, is needed towards implementation of more personalized treatment.

A potential candidate to predict prognosis and illness trajectories is self-disorders. Self-disorders are non-psychotic symptoms that seem to be present years prior to illness onset and to persist after remission from psychotic episodes. Self-disorders describe a fundamental disturbance of consciousness and can be assessed with the *Examination of Anomalous Self-Experiences* (EASE) scale.

We know from previous studies that self-disorders are non-psychotic symptoms central to schizophrenia spectrum disorders.

Objectives: The purpose of this study is to examine if self-disorders are related to clinical and functional outcome as well as illness trajectories and life courses.

We will test if high levels of self-disorders at baseline predict worse outcome in terms of psychopathology, social function, recovery, more malign illness trajectories and life courses for the individual patient.

Additionally, we will examine if self-disorders remain stable over a period of 25 years.
Methods: This ongoing study is a 25-year follow-up study of a cohort of 151 first-admission patients, comprising 51 patients with schizophrenia, 50 patients with schizotypal disorder, and 50 patients with other mental disorders (including bipolar disorder, major depression, anxiety, and personality disorder).
This cohort is the oldest and largest sample in the world that has been assessed for self-disorders. By combining psychosocial and psychopathological history as well as psycho-diagnostic assessments and tests at follow-up examination, with information from the Danish registers, we will obtain as complete a picture as possible of the patients and their illness trajectories and life courses. This will not only be at the point in time of the follow-up, but throughout the last 25 years and gain further knowledge about self-disorders over time. For assessments of psychopathology we will use semi-structured interview using EASE as well using OPCRIT, PANSS, GAF-S and parts of the Bonn Scale for psycho-diagnostic. Social functioning will be measured using the Personal and Social Performance scale (PSP) and GAF-F.
Results: Ongoing study, results are pending.
Conclusions: Ongoing study.

Autoimmune Encephalitis - a diagnosis not to be overlooked in cases of psychosis

F. Ribeirinho Soares[1]*, A. Buinho[1], T. Oliveira[1], M. Fraga[1] and J. Facucho[1]

[1]Departamento de Saúde Mental, Hospital de Cascais, Cascais, Portugal
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.718

Introduction: Autoimmune encephalitis (AE) is a neuroinflammatory condition that often presents with psychiatric symptoms, such as psychosis, mood disturbances, and cognitive impairment, mimicking psychiatric disorders like schizophrenia or bipolar disorder. These symptoms frequently appear before neurological signs, complicating diagnosis and delaying treatment. Early recognition of this condition is fundamental to improve patients outcomes.
Objectives: This review examines the psychiatric manifestations of AE, highlights challenges in differentiating AE from primary psychiatric disorders, and emphasizes the importance of interdisciplinary collaboration.
Methods: A nonsystematic review of literature focusing on the psychiatric presentation of AE.
Results: AE often presents with psychiatric symptoms like hallucinations, delusions, agitation, and mood disturbances, frequently leading to misdiagnoses such as schizophrenia or bipolar disorder. In particular, anti-NMDA receptor encephalitis is associated with severe psychiatric manifestations like psychosis. Diagnosis is based on recognizing the rapid progression of psychiatric symptoms, along with seizures or other neurological signs, and confirming the autoimmune cause through specific autoantibody tests. Early treatment is essential to reverse these psychiatric symptoms. However, delayed diagnosis can result in persistent cognitive and psychiatric difficulties even after treatment. Diagnosing the psychiatric manifestations of AE is challenging due to their overlap with primary psychiatric disorders. However, the rapid onset and progression of symptoms, combined with neurological signs, should prompt clinicians to consider an autoimmune origin. Autoantibodies, particularly those against NMDA receptors, disrupt neurotransmitter systems, explaining the psychiatric features of AE. While psychotropic medications may provide temporary symptom relief, they do not target the underlying immune dysfunction. Timely immunotherapy significantly improves outcomes, and multidisciplinary collaboration between psychiatrists and neurologists is crucial for comprehensive patient care.
Conclusions: AE should be considered in cases of acute psychosis, mood disturbances, or cognitive impairment. Early diagnosis and treatment are key to preventing long-term psychiatric and neurological issues. Greater awareness of AE's psychiatric presentations aids in distinguishing it from primary psychiatric disorders and facilitates timely treatment. Further research is needed to explore the neuroimmune mechanisms behind AE and optimize treatment. Collaborative efforts between psychiatry and neurology are essential for successful patient outcomes.

EPP448

A novel self-report instrument (APPA) to measure psychotic symptoms – development and content validity

B. E. Sportel[1]*, A. Vegter[1], T. van de Giessen[2], G. H. M. Pijnenborg[1,3] and G. D. van Rijsbergen[1]

[1]Psychotic disorders, GGZ Drenthe Mental Health Institute, Assen; [2]Youth and Adolescent psychiatry, GGZ Drenthe Mental Health Institute, Hoogeveen and [3]Clinical and developmental neuropsychology, University of Groningen, Groningen, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.719

Introduction: Various interviews are available to measure psychotic symptoms, including e.g. the Positive And Negative Syndrome Scale (PANSS) when a psychotic disorder is suspected or the Comprehensive Assessment of At Risk Mental States (CAARMS) when there is a suspicion of an increased risk of developing a first psychosis. Conducting these interviews is time-consuming (60-90 minutes) for both patient and professional, and requires a trained interviewer. To our knowledge, no self-report questionnaire is available to measure the degree of psychotic symptoms, while such an instrument is desirable to measure e.g. treatment effects.
Objectives: The aim of the current research: 1. to use gold standard interviews that measure psychosis spectrum problems to develop a self-report questionnaire based on DSM-V, and 2. to examine the content validity of the newly developed instrument.
Methods: Based on the instruments PANSS, CAARMS and SCID-S (Structured Clinical Interview for DSM disorders) the first version of the Asser Psychotische Klachtenlijst (Asser Psychotic Phenomenology Assessment; APPA) was constructed. The APPA assesses symptoms over a three-month time period. To assess content validity, interviews took place with the target population and MH care professionals, followed by alterations based on the results.
Results: Interviews were held with six patients (women: 2; age range: 19-52) with a psychotic disorder, within the first five years after diagnosis. Patients were positive about the questionnaire, thought it was comprehensible and gave a good reflection of their

psychotic problems. Furthermore, they thought the APPA had clear instructions and a good scaling (5-point-Likertscale). Two out of the 36 questions were considered more difficult to comprehend. Eight MH care professionals (one nurse, one nurse practitioner, two psychiatrists, and four psychologists) were interviewed about the APPA. They considered the instrument to be clear and complete with regard to psychotic symptoms, with clear instructions and good scaling. In their opinion two questions were vague, 14 questions contained ambiguous words and five questions were formulated in a complicated way. Based on the findings of the target population and professionals, several questions were adjusted, or reformulated into multiple questions, resulting in a 41-item questionnaire on a 5-point-Likertscale.

Conclusions: The APPA was found to be a comprehensible, clear instrument, giving a good reflection of psychotic problems according to the target population and professionals. The content validity of the APPA was found to be good. As a next step we are collecting data within the target population to establish reliability, this will be followed by a study measuring other psychometric properties, in which the APPA will also be compared to gold standard instruments. The APPA thus far seems a promising instrument for both research and daily practice.

The effect of a mindfulness based-group psychotherapy on stress parameters in schizophrenia spectrum disorders

M. Zierhut[1]*, N. Bergmann[1], S. Koop[1], I. Hahne[1], J. Kraft[2], A. Braun[2], T. M. T. Ta[1], M. Bajbouj[1], N. Thomas[3], P. Chadwick[4], S. Ripke[2], E. Hahn[1] and K. Böge[1]

[1]Clinic for Psychiatry and Neurosciences, Charite - Universitätsmedizin Campus Benjamin Franklin; [2]Clinic for Psychiatry and Neurosciences, Charite - Universitätsmedizin Campus Mitte, Berlin, Germany; [3]Swinburne University of Technology, Melbourne, Australia and [4]University of Bath, Bath, United Kingdom

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.720

Introduction: Recent studies have demonstrated the positive effects of mindfulness-based interventions on stress reduction in healthy individuals. Individuals with schizophrenia spectrum disorders (SSD) often experience elevated stress levels due to multiple factors. According to literature, plasma and saliva levels of oxytocin (OXT) and cortisol can serve as biological stress markers. However, the interaction between mindfulness, stress, and the oxytocinergic system in SSD remains unexplored.

Objectives: This exploratory study investigates the impact of mindfulness-based group therapy (MBGT) on biological stress parameters, including OXT and cortisol levels in plasma and saliva, and changes in psychological stress parameters.

Methods: A blinded, randomized, and controlled study was conducted. Participants were assigned to either MBGT with four weekly sessions in addition to treatment as usual (MBGT+TAU) or only treatment as usual (TAU). Venous blood and saliva samples were collected before and after the MBGT sessions to determine OXT and cortisol levels. Self-reported questionnaires measured stress via visual analogue scales before and after the MBGT sessions.

Results: A total of 48 outpatients with SSD received either MBGT +TAU (n=25) or TAU (n=23). Analyses revealed a significant reduction in subjective stress levels during each MBGT session. After the MBGT sessions, a significant reduction in cortisol levels was observed, which correlated with the reduction in subjective stress experience. During the first session, oxytocin levels significantly increased in the saliva. However, in the last session, there was a significant decrease in oxytocin levels in both blood and saliva. Additionally, the MBGT +TAU group showed significantly lower OXT plasma levels at the end of the intervention compared to the TAU group.

Image 1:

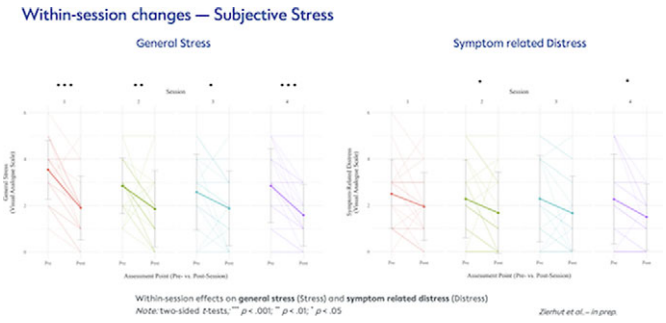

Image 2:

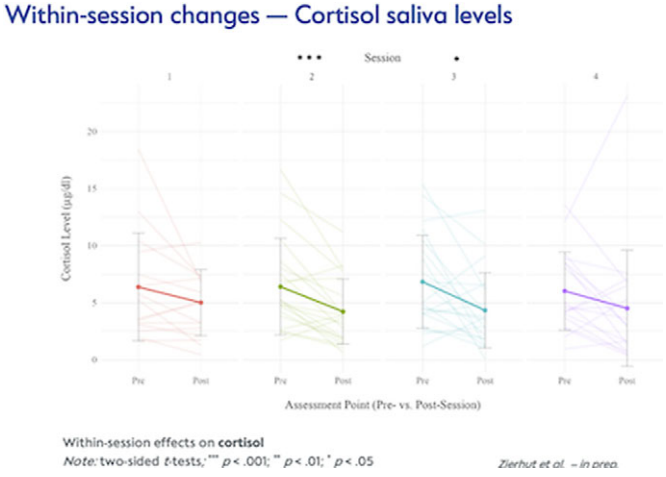

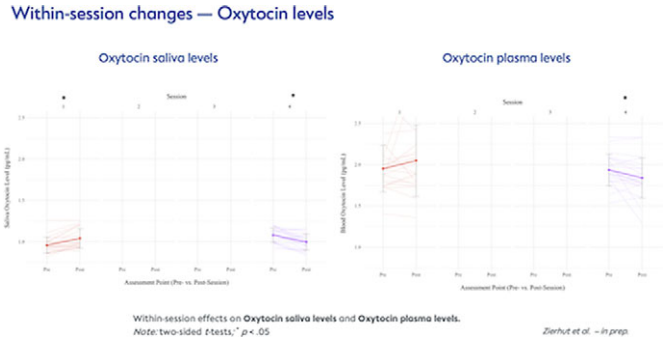

Image 3:

Conclusions: The outcomes of this study provide insights into the potential effects of mindfulness on biological and psychological stress parameters in SSD. Consistent with recent research, we found significant effects on subjective stress and changes in oxytocin and cortisol levels throughout the MBGT intervention. A fully powered trial is needed to determine the efficacy of these findings.

Shattered Dreams: Dysfunctional Families and Suicidal Behaviour among Armenian Adolescents

M. Arsenyan

Department of Child Psychiatry, 'Surb Grigor Lusavorich' Medical Center, Yerevan, Armenia
doi: 10.1192/j.eurpsy.2025.721

Introduction: The family is the cornerstone of a child's physical, emotional, and psychological development (Masteller & Stoop. Servant Pub. 1996; Ubaidi. J Fam Med Dis 2017; 3:059). While a stable family fosters healthy growth and positive interpersonal relationships, a dysfunctional family can lead to severe consequences, especially in adolescence (Kurtz & Derevensky. Can. J. Sch. Psychol 1994; 9(2) 204-216; Holland *et al.* J. Youth Adolesc. 2017; 46(7) 1598–1610). In Armenia, where domestic violence is widespread and underreported due to societal norms prioritising family unity and reputation preservation (Kharatyan & Tovmasyan. Eur. J. Soc. Sci. Educ. Res. 2021; 8 (1) 56-65), research on the effects of dysfunctional family dynamics on adolescent suicidality remains notably scarce.
Objectives: This study explores the role of dysfunctional family structures in suicidal behaviour among adolescents in Armenia.
Methods: A qualitative analysis employing the documentary method was conducted on the patient histories of 67 adolescents hospitalised at 'Muratsan' University Hospital Complex following suicide attempts.
Results: Of the 67 adolescents, 30 had divorced parents, and 37 had intact families. Five key themes—pathological, authoritarian, conflict-driven, chaotic, and neglectful family environments—emerged, highlighting the development of adolescent suicidal behaviour. Adolescents from pathological families, where one or both parents struggled with substance abuse or mental health conditions, frequently witnessed and experienced ongoing domestic violence. In authoritarian families, adolescents were subjected to coercive and controlling behaviour, while those from conflict-driven families were often caught in intense interpersonal strife or between feuding, divorced parents. In chaotic families, parents were unable to meet the adolescents' emotional needs due to their overwhelming focus on financial responsibilities and coping with the fallout of divorce. In neglectful families, adolescents experienced a profound lack of parental involvement and support, often feeling abandoned. These dysfunctional family environments fostered suicidal behaviour, with adolescents attempting suicide as they 'couldn't bear their situation any longer', wanted to 'escape reality', 'couldn't see a way out', 'didn't feel needed by their parents', 'couldn't find a reason to live' and 'wished to die'.
Conclusions: The study revealed that adolescent suicidality arose within dysfunctional family environments characterised by ongoing exposure to domestic violence, coercive and controlling behaviour, conflicts, parental neglect, and a lack of emotional support. These findings highlight the critical need for targeted interventions to support at-risk youth, emphasising the urgency of addressing domestic violence against women and children in Armenia and assisting parents in fostering a caring and safe family environment.

Thyroid hormone levels are linked to history of suicidal behavior in individuals with anxiety and mood disorders

V. Jakienė[1], N. Raškauskienė[1], A. Podlipskytė[1], N. Mickuvienė[1], V. Adomaitienė[2], E. Zauka[2], G. Mačys[2] and V. Steiblienė[2]*

[1]Laboratory of Behavioral Medicine, Neuroscience Institute, Lithuanian University of Health Sciences, Palanga and [2]Clinic of Psychiatry, Lithuanian University of Health Sciences, Kaunas, Lithuania
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.722

Introduction: The relation between thyroid function and depression has long been recognized. However, studies analyzing coexistence of thyroid dysfunction and suicidal behavior still offer contradictory results. Thyroid hormones that may play an important role in suicidal behavior have not been thoroughly investigated in the sample of individuals with comorbid anxiety and mood disorders (AMD).
Objectives: The aim of this cross-sectional study was to identify potential associations between thyroid function and suicide attempts (SA) in individuals with AMD.
Methods: This study comprised 147 consecutive participants (mean age 42.4±13.1 years; 69% women). Thirty-five percent (n=51) of the sample was hospitalized after a suicidal attempt, 34 percent (n=50) patients with AMD and without a history of SA, and 31 percent (n=46) individuals without a life time history of mental disorders or suicidal attempt (control group). All participants were interviewed for current psychiatric diagnoses and suicidal behavior using the Mini International Neuropsychiatric Interview. The biochemical blood tests were performed for the concentrations of free thyroxine (FT4), free triiodothyronine (FT3) and thyroid stimulating hormone (TSH). All data were reported as means, standard deviations, or medians (interquartile range [IQR]). Analysis of variance (ANOVA), chi-square test, independent samples t-test, Kruskal-Wallis test, were used for the group comparisons. Multivariable logistic regression analyses were used to assess the associations between thyroid hormones parameters and SA.
Results: All participants had serum FT4, FT3 and TSH level within normal range. Patients with AMD and SA were more likely to be younger than patients with AMD only and the control group (36.1 ± 13.6 vs. 41.5 ± 11.9 and 48.4±12.1 years; p<0.001). There were no significant differences according to gender, BMI, mean values of TSH and FT4 between groups. In our study, FT3, but not the other thyroid axis hormones, was independently associated with suicidal behavior. Patients with AMD and SA had lower FT3 levels in comparison to patients with AMD without SA and the control group (5.20 (0.65) pmol/L vs. 5.52 (0.62) and 5.65 (0.71, p=0.005)). A multivariable logistic regression revealed that FT3 levels of female SA were significantly lower than non-attempters (4.92 (0.64)

pmol/L vs. 5.42 (0.71), p=0.029) and significantly lower than male-attempters (5.61 (0.61), p<0.001). We not found any significant differences with regard to FT3 levels between male SA and non-attempters and controls.
Conclusions: Lower FT3 concentrations, even within the normal reference range, were related to SA in female gender, but not male. This finding supports the importance of evaluating FT3 levels in clinical decision-making on suicide risk of patients with AMD.

Euthanasia and assisted suicide of patients with psychiatric disorders in the Netherlands between 2021 and 2023

M. Lucente[1]*, P. Pietrini[2] and I. A. Cristea[1]

[1]General Psychology, University of Padua, Padua and [2]IMT Scuola Alti Studi Lucca, Lucca, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.723

Introduction: Medical-assistance in dying, either by euthanasia or assisted suicide (EAS), for mental disorders as the main reason is a complex and controversial practice. owing to the inevitable tension between the seriousness of the mental disorder and the requirement that the patient can make a well-reasoned decision. Systematic investigations of the characteristics of the patients (disorders, previous treatment, comorbidities) and the procedures of granting EAS for mental disorders have been limited.
Objectives: To describe the characteristics of patients receiving EAS for psychiatric conditions in the Netherlands between 2021 and 2023.
Methods: We reviewed psychiatric EAS case summaries made available publicly online by the Dutch regional euthanasia review committees between 2021 and 2023. All summaries were translated with ChatGPT and those with mental disorders as the main reason were selected. We extracted information about the patients' clinical and social characteristics, type of treatments previously administered, how physicians handled patients' requests and the euthanasia review committees' assessments of the physicians' actions.
Results: Thirty-six cases were identified. Of these, 86% (n = 31) were women. Regarding age, 30.5% (n = 11) were 70 years or older, 36% (n = 13) were 50 to 70 years old, 16.6% (n = 6) were 30 to 50 years old and 16.6% (n = 6) were less than 30 years old. Most had chronic conditions, with histories of attempted suicides (39%; n=14) and psychiatric hospitalizations (69%; n=25). One third (n = 12) of patients were described as socially isolated. Depressive disorders were the primary psychiatric diagnosis in 27.7% (n = 10) of cases. Other conditions included personality disorders (19.4%; n=7), particularly borderline (11%; n=4), somatoform disorders (17%; n=6) and posttraumatic stress disorder (11%; n=4). Comorbidities with medical conditions or physical symptoms were present in 27.7% (n = 10) of cases. Most frequent treatments previously administered were medications and psychotherapy, particularly cognitive behavioral (19.4%; n=7) therapy and EMDR (14%; n=5). Fifty percent (n = 18) of patients received EAS from Euthanasia Expertise Center physicians, 17% (n=6) from their general practitioner. In 11% (n = 4) of the cases there was disagreement among consultants.
Conclusions: Individuals who received EAS for psychiatric reasons in the Netherlands between 2021 and 2023 were mostly women, with complex and chronic psychiatric conditions, often with medical comorbidities. Despite the fact that EAS requires agreement from two independent physicians, there were instances where it was performed without it.

Disclosure of Interest: None Declared

EPP455

Monocyte-to-lymphocyte ratio and further inflammatory parameters as potential biomarkers of suicide risk in bipolar affective disorder

B. Pethő[1]*, T. Tényi[1], R. Herold[1], D. Simon[2], T. Tóth[3], C. Molnár[1] and M. Á. Kovács[1]

[1]Department of Psychiatry and Psychotherapy; [2]Department of Immunology and Biotechnology and [3]1st Department of Internal Medicine, University of Pécs, Clinical Centre, Pécs, Hungary
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.724

Introduction: Suicide is an unresolved issue in psychiatry to this day. Suicide risk (SR) is highest for psychiatric patients with bipolar affective disorder (BD). Recent studies suggest an immunological dysregulation in the background of suicidality, and in accord with former results, our research group has previously found monocyte-to-lymphocyte ratio (MLR) and further inflammatory parameters to be reliable indicators of SR in patients with major depressive disorder.
Objectives: Determining SR remains a challenge for clinicians. Alterations in the number and ratio of inflammatory cells have been proposed as potential biomarkers of SR, therefore our aim was to investigate changes of these parameters in relation to acute and long-term SR in BD patients.
Methods: In our restrospective study, we investigated laboratory parameters of psychiatric inpatients diagnosed with BD between January 2020 and June 2024. Data was collected regarding the following parameters: white blood cell, neutrophil, lymphocyte, monocyte and platelet count, MLR, neutrophil-to-lymphocyte (NLR) and platelet-to-lymphocyte ratio (PLR), C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), red blood cell distribution width (RDW) and mean platelet volume (MPV). Individuals with recent (≤ 48 hours prior) suicide attempt (SA) (n = 21) and with past (> 48 hours prior) SA (n = 16) represented the high SR group (n = 37). BD patients with no history of SA (n = 79) composed the intermediate SR group. Statistical analyses were carried out using the GraphPad Prism 10.3.1 programme.
Results: We found a significant increase in MLR (p = 0.0021, Fig. 1), monocyte count (p = 0.0045), CRP (p = 0.0036), ESR ($p \leq 0.0001$) and MPV ($p \leq 0.0001$) in patients with recent SA compared to those with no history of SA. Comparing high and intermediate risk patients, MLR (p = 0.012, Fig. 2), monocyte count (p = 0.0293), CRP (p = 0.0499, Fig. 3), ESR (p = 0.0009) and MPV (p = 0.008) remained elevated in the former group. We found no significant differences regarding the rest of the parameters. According to ROC analysis, the probability of the significant results was outstanding in case of ESR and acceptable for the rest of the parameters.

Image 1:

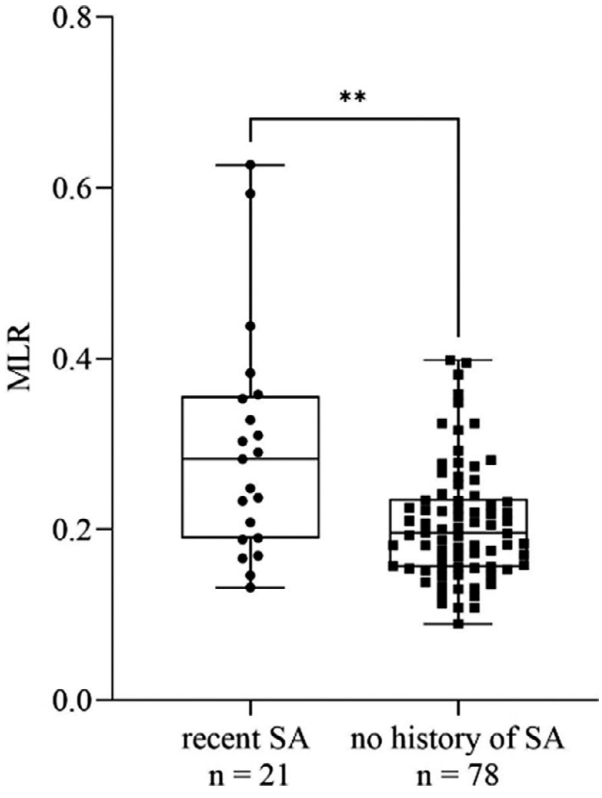

Image 2:

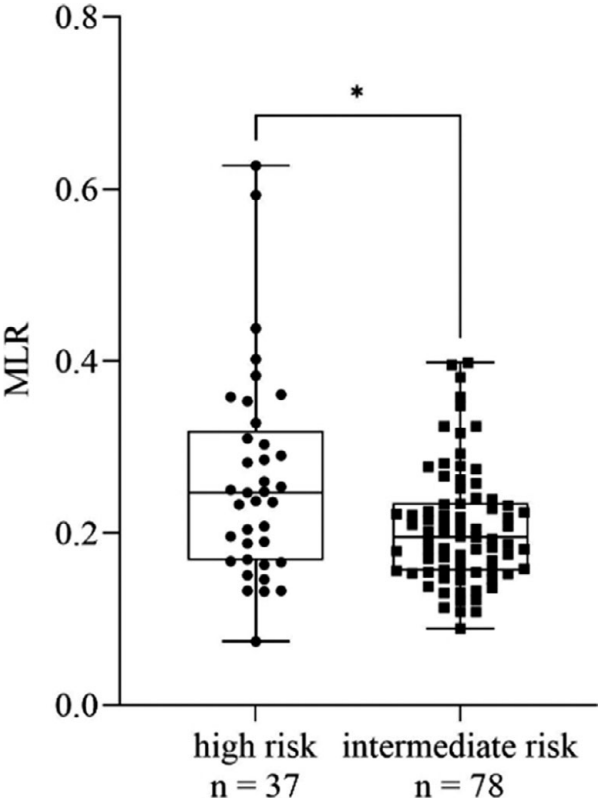

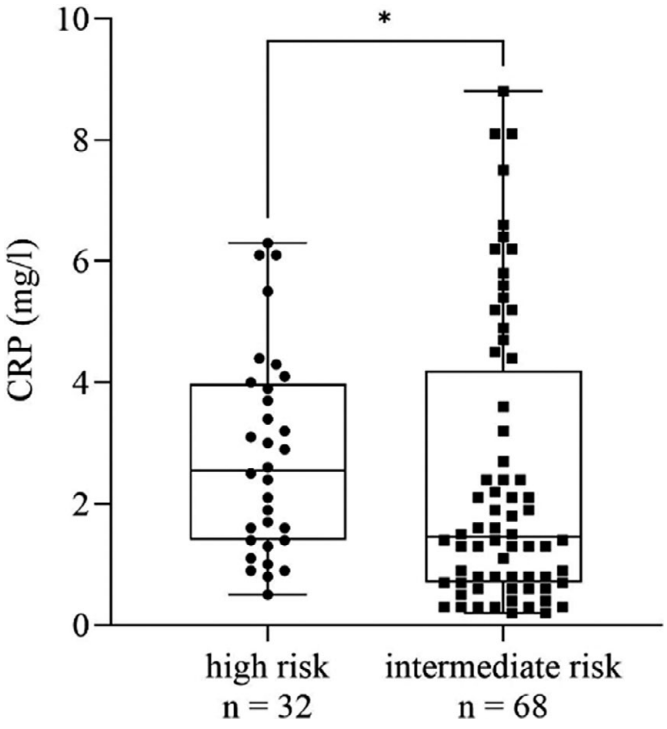

Image 3:

Conclusions: As implied by previous research, immunological mechanisms may contribute to the emergence of suicidality. Investigating BD patients as the subgroup most at risk, we found MLR, monocyte count, CRP, ESR and MPV to show significant alterations in recent attempters, signalling acute SR. Furthermore, all of these markers were significantly elevated in high risk patients, therefore they may be indicative of long-term SR. Changes in these inflammatory markers further strengthen the assumption of immunological processes in the background of suicidality, and these parameters may serve as potential future biomarkers of SR.

The study was supported by the EKÖP-24-3-II-PTE-168 project.

Highlights from Suicide Prevention Research in 2024

S. Tanyeri Kayahan[1], C. M. Platsa[2], M. Batković Šošo[3], M. Spasić Stojaković[4], S. Gomes Rodrigues[5] and F. Kraxner[6]*

[1]Psychiatry, Republic of Türkiye Yalvaç State Hospital, Isparta, Türkiye; [2]Psychiatry, Barnet, Enfield and Haringey Mental Health NHS Trust, London, United Kingdom; [3]Psychiatry, General Hospital of Dubrovnik, Dubrovnik, Croatia; [4]Psychiatry, Theodor-Wenzel-Werk, Berlin, Germany; [5]Child and Adolescent Psychiatry, Centro Hospitalar Universitario de Santo Antonio, Porto, Portugal and [6]Psychiatry, Hospital Affoltern am Albis, Zürich, Switzerland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.725

Introduction: Suicide is a worldwide leading cause of mortality in youth, estimated to be the second leading cause of death for 10 to 24-year-olds. Increasing suicidality rates prompted worldwide

national efforts to implement extensive suicide prevention plans. Those include crisis helplines, brief interventions such as safety planning and lethal means counseling, along with gatekeeper training and social prescribing.
Objectives: This rapid review aimed to highlight the focus on suicide prevention-related research and review various preventive strategies reported throughout 2024.
Methods: Participants from the European Psychiatric Association 2022 Summer School on "Focus on Suicide Behaviours - One Step Beyond" gathered and conducted a rapid, selective review of original research and review articles on the PubMed database using the search term "suicide prevention" with a time restriction to January-September 2024. Of 1529 results, 14 were selectively included depending on their specific discussion topics, such as suicide prevention in the perinatal period, social prescribing, social support system, and social network interventions, and crisis helplines. The main findings of the articles were summarized in specific brief sections.
Results: Suicide being one of the leading causes of maternal mortality, the need for appropriate interventions for preventing maternal suicide was indicated (Gelabert *et al.* Matern Child Health 2024; 28(9) 1443-1453). Another topic of interest regarding the suicide rates among individuals without a mental disorder diagnosis being as high as one in five suicide attempters emphasized the scarcity of identifying this population's risk factors (Oquendo *et al.* JAMA Psychiat 2024; 81(6) 572). A focus on crisis helplines as promising tools with a potential supportive impact on suicide prevention was obtained. Social prescribing, social support systems, and social network interventions were also identified as promising intervention strategies, particularly in adolescents (Dash *et al.* Front Public Health 2024; 12 1396614, Zheng *et al.* Prev Med Rep 2024; 39 102654). Gatekeeper training that aims to train community members to identify high-risk individuals and facilitate timely referrals and adequate support were found to have positive effects on gatekeeper behaviours (Spafford *et al.* Prev Sci 2024).
Conclusions: Recent research in suicide prevention includes an emphasis on adolescent and perinatal suicidality. The evaluated interventions involve crisis helplines, social network interventions, and gatekeeper training. Meanwhile, this review was focused on specific aspects of suicide prevention; thus, its results are limited. Considering particular methodological and ethical challenges in studying the efficacy of suicide prevention interventions, further research encapsulating new approaches is needed.

The burden of suicide in the Emergency Room: a 3-year single center experience

C. Mauceri[1*], A. Prebilic[1], L. Isabella[1], F. Gavelli[1,2], E. Gambaro[1,3], C. Gramaglia[1,3] and P. Zeppegno[1,3]

[1]Department of Traslational Medicine, Università degli Studi del Piemonte Orientale; [2]Emergency Medicine Unit and [3]S.C. Psichiatria, AOU "Maggiore della Carità", Novara, Italy
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.726

Introduction: Suicide is one of the leading causes of death worldwide with more than 700.000 deaths per year. Its risk factors encompass socioeconomic elements, psychological burdens and mental health disorders, and biological variables. Still, the understanding of different risk factors and their interplay remains incomplete. Suicide attempts are estimated to be from ten to forty times more frequent than suicide deaths.
Objectives: The main objective of this ongoing research is to investigate socio-demographic and clinical variables of suicidal patients in an emergency setting. The secondary objective is to analyze risk factors, clinical presentation and outcome comparing patients with single or repeated psychiatric assessments in the emergency room.
Methods: This study retrospectively analyzes data from patients who underwent psychiatric evaluation in the ER setting following suicide ideation and suicide behavior, at the "Maggiore della Carità" hospital in Novara, from January 2021 to January 2023. Initial descriptive statistics have been performed using frequencies and percentages. Additional statistical analyses on collected data are in development.
Results: Preliminary results showed that 1674 patients were admitted at the ER for psychiatric consultation in the three-year period, 177 of whom evaluated for SI and SB (females = 116, 66.3%) mainly from Italy (n = 151, 88.3%). The mean age was 41.26 ± 18.54 years (range = 16-88 years). The majority of patients were unmarried (=79, 53.0%), employed (=40, 34.5%), with lower secondary education (=36, 38.3%) and living with family (=108, 71.5%). A pre-existing psychiatric condition was reported nearly in two-thirds of individuals (=129, 74.1%); linked predominantly with personality disorders (=47, 34.6%), major depressive disorders (=30, 22.1%) and anxiety disorders (=13, 9.6%). The most common methods for suicidal attempts were overdose with medication (=106, 60.6%) and self-inflicted injuries (=31, 17.7%). A single psychiatric assessment was conducted nearly in the totality of cases (=147, 86.4%), while a minority of records consisted of repeated access from the same patient (=30, 13.6%).
Conclusions: Initial findings are in line with current literature on suicide risk factors. Further statistical analyses will be conducted to search for known associations between risk factors, and to shed light on the most important elements to consider when evaluating suicide ideation and suicide behavior risks in an emergency setting.

Emotional responses to suicidal patients and burnout syndrome: the impact of physicians' mental health on clinical evaluation

R. T. Monteiro[1,2*], P. B. Bolzan[1], T. P. Comissoli[1], G. I. Zanella[3] and Y. A. Ferrão[1,2]

[1]Universidade Federal de Ciências da Saúde de Porto Alegre; [2]Serviço de Psiquiatria, Hospital Materno Infantil Presidente Vargas (HMIPV), Porto Alegre, Brazil and [3]Vrije Universiteit Amsterdam, Amsterdam, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.727

Introduction: Clinicians' emotional responses to patients (countertransference) have a significant impact on treatment outcomes. This process is particularly relevant when assessing patients at risk for suicide, as they elicit powerful feelings such as sadness, disapproval, hostility, and distance. These feelings influence risk assessment and have not been the subject of many research studies. Burnout syndrome is a state of complete exhaustion related to work

and represents an important factor that impairs the decision-making process. However, there is little existing literature on the impact of physician burnout on emotional responses to suicidal patients. We hypothesized that burnout impacts clinicians' emotional responses to suicidal patients.
Objectives: This study aims to identify whether burnout influences physicians' emotional responses (countertransference), comparing psychiatrists and non-psychiatrists.
Methods: An anonymous web-based survey was conducted using the software REDCap and employed a snowball sampling method. Participants were volunteers and could withdraw at any time. The study was approved by the University Ethics Committee. The survey included the Informed Consent Form (ICF), a Sociodemographic Questionnaire, the Burnout Assessment Tool (BAT), and the Rating Scale for Countertransference (RSCT), which evaluates the main emotional responses (approach, indifference, or rejection). Other scales were included but are being developed in separate studies.
Results: Of the 210 respondents, 179 (85.2%) completed the survey: 108 (60.3%) were female, and 166 (92.7%) self-identified as white-colored-skin. The mean age was 37.22 years (SD = 12.33), with a median of 6 years (range: 0 to 48) of professional experience. Among the respondents, 65 (36.3%) were medical residents, and 112 (62.6%) were already specialists; of these, 54 (48.2%) identified as psychiatrists. Physicians with a lower age (r = -0.346), lower income (r = 0.226), and less time since graduation (r = 0.332) experienced more burnout. When evaluating physicians in general, those who experienced burnout tended to exhibit emotional responses of indifference (r = 0.259). When comparing medical specialties, psychiatrists reported less burnout than non-psychiatrists.
Conclusions: We found preliminary evidence that burnout syndrome compromises emotional responses (countertransference), as physicians who experience burnout exhibit more indifference and less approach when evaluating suicidal patients.

Association between physician's sexual orientation, gender and their emotional response when evaluating suicidal patients

R. T. Monteiro[1,2*], G. I. Zanella[3], T. P. Comissoli[1], P. B. Bolzan[1] and Y. A. Ferrão[1,2]

[1]Universidade Federal de Ciências da Saúde de Porto Alegre (UFCSPA); [2]Serviço de Psiquiatria, Hospital Materno Infantil Presidente Vargas (HMIPV), Porto Alegre, Brazil and [3]Vrije Universiteit Amsterdam, Amsterdam, Netherlands
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.728

Introduction: Despite several efforts and public awareness campaigns, suicide rates are still rising in some countries, being third leading cause of death among 15-29-years-old. Some populations are at higher risk for suicidal behavior, such as LGBTIQ+ people and physicians. We found no literature regarding a possible association between physicians emotional response to suicidal patients (countertransference), sociodemographic factors and physicians mental health.
Objectives: Identify a possible association between sociodemographic factors, countertransference and Burnout Syndrome.
Methods: An anonymous web-based survey was implemented through the software REDCap, collected by snowball sampling. Participants were volunteers and could withdraw at any time. The study was approved by the University Ethics Committee. The survey consisted of the Informed Consent Form (ICF), Sociodemographic Questionnaire, Rating Scale for Countertransference (RSCT), which evaluate the main emotional responses (approximation, indifference or rejection). Scales also included Burnout Assessment Tool (BAT) and the Interpersonal Reactivity Index of Davis. Other scales were included, but are being developed in other studies.
Results: From the 210 respondents, 179 (85.2%) completed the query: 108 (60.3%) were female; 166 (92.7%) were self-declared white-colored skin; 139 (77.7%) had a sexual partner. The mean age was 37.22 (SD=12.33), 65(36.3%) were medical residents; 112 (62.6%) were already specialists, 54 (48.2%) of those, declared to be psychiatrists. Indifference varies according to sexual orientation (p = 0,002), even when controlling for burnout (p < 0,001). Bissexual physicians had lower indifference rates than the other groups (Heterosexual: N=104, M 1,52, SD 1,52, CV 0,998; Homosexual: N=15, M 2,60, CV 0,870; Bisexual: N=17, M 0,64, SD 0,20, CV 1,332). Females had higher approximation rates when compared to male (Male: N = 53; M 15,71; SD 5,77; Female: N = 90; M 17,94; SD 3,70; p = 0,006). There's no difference between gender when evaluating indifference and rejection. Homosexual and bisexual physicians experience more burnout (Heterosexual: N = 118, M 49,94, SD 14,5. Homosexual: N = 16; M 60,0; SD 15,2. Bisexual: N = 18; M 59,6; SD 4,6). F (2) = 5,51; p = 0,05.
Conclusions: We find preliminary evidence that sexual orientation could influence emotional response when evaluating suicidal patients. Women have higher approximation. Both results remain the same when controlling for Burnout syndrome.

Quality of life and Magnetic resonnance imaging(MRI) in multiple sclerosis

N. Ben Hamed[1*], S. Cherif[2], A. Aissa[1], A. Souissi[3] and R. Jomli[1]

[1]psychiatry A; [2]Psychiatrt A, Razi hospital and [3]neurology department, LR18SP03 and Clinical Investigation Center Neurosciences and Mental Health - university hospital center Razi, Manouba, Tunisia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.729

Introduction: Multiple sclerosis (MS) is a chronic neurological disorder that can profoundly affect patients' quality of life due to its diverse symptoms and disease progression. MRI findings are critical in assessing the extent of neurological damage and may correlate with various aspects of patients' health and well-being.
Objectives: identify the relationship between MRI findings and quality of life in individuals with MS.
Methods: A cross-sectional study was conducted in the neurology department of Razi University Hospital (Tunisia) between October 2023 and June 2024. Patients with a diagnosis of MS based on the 2017 McDonald criteria were recruited, excluding those with active disease relapses. Participants completed questionnaires covering sociodemographic data, medical history, disability status, clinical and radiological characteristics. Quality of life was assessed using the SF-36 and the Multiple Sclerosis Quality of Life (MSQoL-54) scales.

Results: A total of 83 patients with MS were recruited, with ages ranging from 19 to 66 years. The study population had a predominantly female sex ratio of 3.4. The majority of participants (75.9%) were from urban areas, and 74.7% had a university-level education. Moreover, 49.1% were married, and 60.2% were employed. Regarding medical history, 40.3% had a comorbid condition, and 30.1% had a psychiatric history. The mean age at disease onset was 26 ± 10 years. First-line treatments were prescribed to 27.7% of patients. Second-line treatments were prescribed to 69.9% of patients.
The mean overall score on the SF-36 scale was 53.56 . According to MSQ ol54, the most affected domains were sexual function, physical health limitations, and sleep. The least affected domains were pain, social function, and sexual satisfaction.The SF-36 mean score decreased from 50.59 in patients with more than 10 lesions to 21.37 in those with fewer than 10 lesions, with a statistically significant difference ($p = 0.012$). We found a significant relationship between a higher number of lesions (>10) and the dimensions of physical health ($p = 0.007$), emotional well-being ($p = 0.027$), perception of health ($p = 0.025$), social function ($p = 0.017$), distress ($p = 0.049$), cognitive function ($p = 0.038$), and overall quality of life ($p = 0.029$). Thalamic lesions were associated with the dimension of distress ($p = 0.048$). The presence of new lesions in the most recent follow-up MRI was associated with emotional well-being ($p=0.018$).
Conclusions: The study highlights a significant correlation between MRI findings and quality of life inpatients with MS. Understanding this relationship is crucial for developing targeted treatment strategies that address both the physical and psychological aspects of the disease. By integrating MRI assessments into routine care, healthcare providers can better support the well-being of individuals living with MS and tailor interventions to their specific needs.

Using EEG to challenge ASD heterogeneity: Stratification of brain functional connectivity reveals clinically meaningful subgroups of ASD

B. Rodriguez-Herreros[1]*, A. Mheich[2,3], S. Yassine[4], J. M. A. Osório[1], S. Richetin[1], V. Junod[5], L. Mendes[1], K. Gschwend[1], V. Aeschbach[1], L. Arnold[1], D. Romascano[1], P. Yu[1], M. Jequier Gygax[1], A. M. Maillard[1], M. Hassan[3,6] and N. Chabane[1]

[1]STSA, CHUV, Lausanne, Switzerland; [2]Université de Rennes; [3]MINDIG, Rennes, France; [4]Nuffield Department of Clinical Neurosciences, Oxford University, Oxford, United Kingdom; [5]Département femme-mère-enfant, CHUV, Lausanne, Switzerland and [6]School of Science and Engineering, Reykjavik University, Reykjavik, Iceland
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.730

Introduction: Heterogeneity in both the etiology and the phenotypic presentation of autism spectrum disorder (ASD) poses a major challenge to clinical and translational research. Attempts to stratify individuals with ASD have been primarily based on behavioral criteria, but clinical subtyping is blind to the underlying neurobiological mechanisms and has limited predictive value of the forthcoming developmental path. Yet, it is still unclear whether and how atypical brain functional connectivity can account for individual differences across ASD-related symptomatology and behaviors.
Objectives: The goal of the study was to identify clinically meaningful subgroups of young children with ASD based on distinctive patterns of brain functional connectivity, to better understand the neural substrates underlying ASD heterogeneity.
Methods: We combined resting-state EEG data from 4 independent datasets on 541 children with ASD aged 2-12 years to estimate and stratify brain functional connectivity measures. We performed an unsupervised clustering analysis of the cortical network properties, using data-driven similarity network fusion and source-based spectral analysis. We then compared the clinical profile of the identified clusters to define symptom-linked connectivity dimensions.
Results: We identified four subgroups of ASD children with distinct cortical network properties, mainly mapped in the fronto-parietal and precentral cortices for the alpha band, and in the middle temporal cortex for beta band. These four clustered dimensions of functional connectivity were associated to distinctive different clinical symptom profiles, specially with respect to cognitive level, adaptive behavior and motricity.

Image 1:

Conclusions: Our findings shed light on atypical brain network topology conferring risk for specific phenotypic manifestations of ASD, which may implicate unique underlying neurobiological mechanisms. Cross-validation stability hints at a solid stratification model to challenge ASD heterogeneity. Collectively, the stratification of well-defined neural signatures that give rise to the clinical heterogeneity of ASD has the potential to provide more accurate prognosis and help to select the optimal strategy for therapeutic intervention.

Neuroanatomical and neuroimaging biomarkers of "MRI-defined vascular depression"

A. Starcevic[1]*, B. Vucinic[2], F. Starcevic[2], B. Starcevic[3] and M. Stojanovic[4]

[1]Anatomy; [2]University of Belgrade; [3]University Clinical Center of Belgrade, Belgrade and [4]Private practice Ortodent, Paracin, Serbia
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.731

Introduction: "MRI-defined vascular depression" suggests that vascular lesions and small vessels disease induce depression by disruption of frontal–subcortical–limbic networks.Vascular depression is associated with disruption or cortico-striato-pallido-thalamo-cortical pathways or their modulating systems.
Objectives: Based on clinical correlates and structural MRI findings we aim to evaluate causal relationship between specific brain changes

and its related lesions in localization and number, through visual rating scales semi-automated and fully automated volumetric methods of specific software packages as part of deep machine learning.
Methods: We have included 50 T2/FLAIR MRI brain scanned images, 30 patients (both genders) with late-onset vascular depression and 20 controls. In all subjects, T2/fluid-attenuated inversion recovery (FLAIR) sequences of the brain were collected during a single session using a 3 Tesla scanner (Siemens Skyra Medical Systems). FLAIR-white matter hyperintense lesions were identified and quantified using a local thresholding segmentation technique using specific software. FLAIR lesion volume and number was reported for the whole brain and for each hemisphere separately, without distinction between deep and periventricular.
Results: There is statistical significance in total number and total regional volume of interest in brains of patients with late-onset vascular depression compared to controls ($p<0.05$). Median number of white matter hyperintensities was 14 per patient, and white matter hyperintensities median volume was 721 mm3. No difference was found between right and left hemisphere in terms of number ($p>0.05$) and volume ($p>0.05$) of white matter hyperintensities. Statistical significance was faound in volume and localisation of lesions in the brain ($p<0.05$).

Image 1:

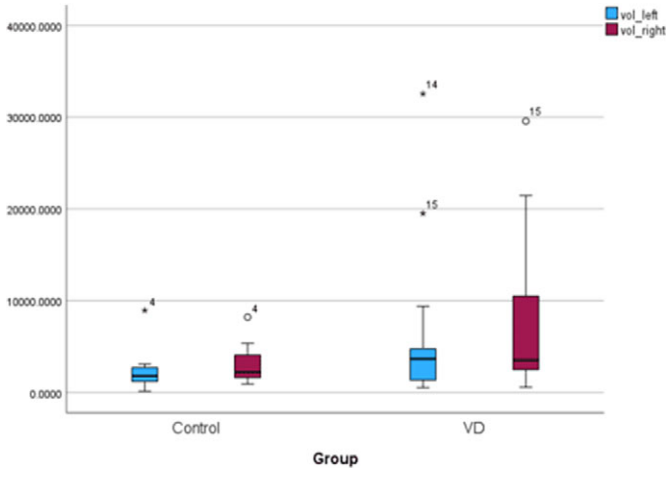

Image 2:

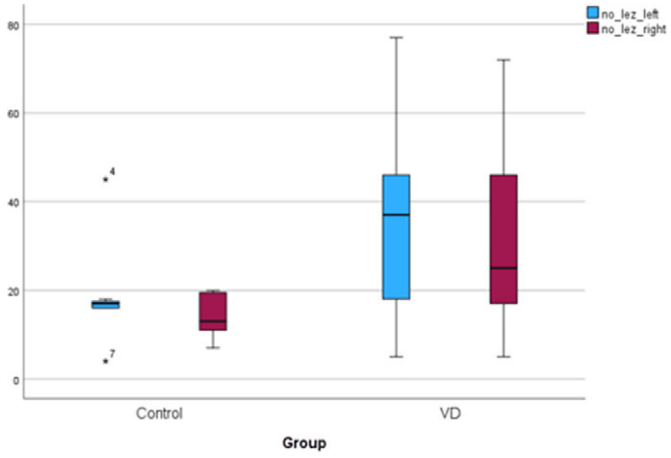

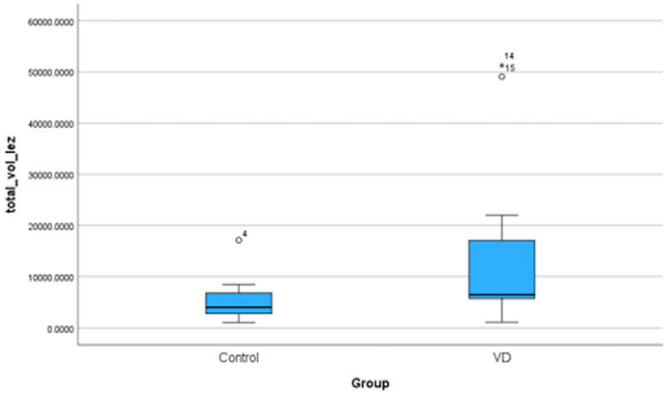

Image 3:

Conclusions: Higher burden of white matter hyperintensities in patients with vascular depression could be associated with progression of clinical depressive symptomatology as well as with severity of brain damage.

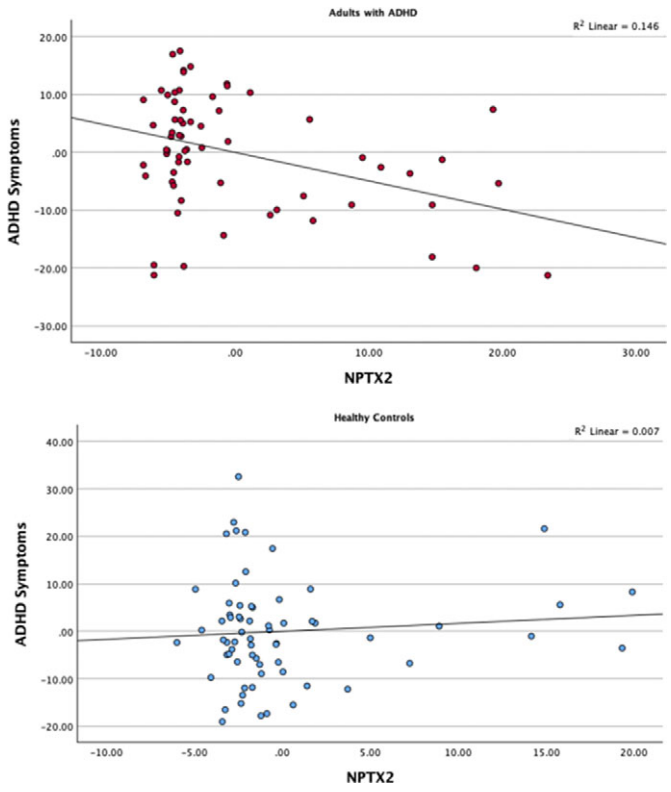
Association Between Neuronal Pentraxin 2, ADHD Symptoms, and Executive Functioning in Adults with ADHD: A case-control study

S. Kaya[1], A. Kandeğer[1]*, R. Kocabaş[2], A. E. Yorulmaz[2], B. Sağlıyan[1] and Ö. Bayırlı[1]



[1]Psychiatry and [2]Biochemistry, Selçuk University, Konya, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.732

Introduction: Neuronal pentraxins (NPTXs), particularly NPTX2, play a key role in glutamate modulation and the stabilization of AMPA receptors, influencing synaptic plasticity. Studies have shown a positive correlation between NPTX2 levels and neurocognitive function in neurodegenerative diseases, and it has been proposed as a potential biomarker for synaptic degeneration (San José *et al.* J Neural Transm 2022; 129 207-230). However, the role of NPTX2 in the etiology of ADHD has not been explored in human samples.
Objectives: This study aims to investigate the relationship between NPTX2 levels and ADHD symptoms in adults with ADHD, while also exploring the potential impact of NPTX2 on executive functions, which are frequently impaired in this population.
Methods: Adults with ADHD who were medication-free and had no comorbid psychiatric diagnoses, along with a similar control group with no psychiatric diagnoses, were included in the study. All participants were diagnostically assessed using the Structured Clinical Interview for DSM-5 Disorders-Clinician Version. Participants completed measurements related to both ADHD and comorbid conditions. In addition, participants underwent a battery of neuropsychological tests, including the Stroop Test, Cancellation Test, Serial Digit Learning Test, Wisconsin Card Sorting Test, and Judgment of Line Orientation Test. The serum samples obtained after centrifugation were stored at -80°C

until the time of analysis, at which point NPTX2 levels were measured using the ELISA method. Informed consent was obtained from all participants, who voluntarily agreed to participate. The study was approved by the Local Ethics Committee of Selçuk University under decision number 2023/495.

Results: The study included 79 adults with ADHD and 70 healthy controls. Among the participants, 57.7% (n=86) were female, with a mean age of 23.50 ± 4.37 years. Both groups were comparable in terms of age, gender, total years of education, and body mass index. Individuals with ADHD showed higher levels of ADHD- and comorbidity-related symptoms, as well as poorer executive function profiles, compared to healthy controls. NPTX2 levels were significantly elevated in the ADHD group. Significant positive correlations between NPTX2 levels and clinical and neurocognitive data were observed in the ADHD group, but not in the control group. Finally, linear regression analyses conducted separately for each group revealed significant F values, showing that in adults with ADHD, NPTX2 levels were significantly associated with ADHD symptoms independent of age, gender, years of education, and anxiety/depression scores, whereas this relationship was not observed in healthy controls (Image 1).

Image 1:

Conclusions: These results highlight the need for further research into the role of NPTX2 and other neuronal pentraxins in ADHD and suggest that NPTX2 may serve as a biological marker for this disorder.

Disclosure of Interest: None Declared

Anti-NMDA Receptor Encephalitis following Herpes Simplex Encephalitis presenting as Mania with Psychotic Features: Case Report

I. M. Lopes[1]*, D. Seabra[2], G. Santos[1], N. Ramalho[1], T. Coelho Rocha[1], J. Alves Leal[1], J. F. Cunha[3], J. Moura[1], D. Santos[1], A. Garcia[1], M. Rosa[1] and C. Pires[1]

[1]Psychiatry, ULS Arco Ribeirinho; [2]Psychiatry, USL Arco Ribeirinho and [3]Psychiatry, ULS Barreiro, Barreiro, Portugal

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.733

Introduction: Herpes Simplex Encephalitis (HSE) and anti-NMDA receptor autoimmune encephalitis (ANMDARE) are severe neurological conditions that can lead to significant psychiatric symptoms. While these conditions commonly cause cognitive and behavioral disturbances, mania with psychotic symptoms is an uncommon manifestation. Understanding this rare presentation is crucial for accurate diagnosis and management.

Objectives: To describe a case of mania with psychotic symptoms in a 33-year-old woman approximately one month after Herpes Simplex Encephalitis (HSE), further complicated by anti-NMDA receptor autoimmune encephalitis.

Methods: We conducted a detailed review of the clinical process and heteroanamnesis from family reports. A non-systematic literature review was performed using the terms "encephalitis," "mania," "psychosis," "herpes simplex," and "anti-NMDA" in the PubMed®/MEDLINE® database.

Results: A 33-year-old woman, seven months postpartum with no prior psychiatric history, presented with psychomotor agitation, distractibility, elevated mood, verbose speech, tachypsychia, impulsivity, verbal perseveration, insomnia, and mystical and persecutory delusions, including auditory-verbal hallucinations, starting 15 days after discharge from hospitalization for HSE. Her subsequent hospitalization revealed severe and fluctuating behavioral changes, significant memory deficits, and spatial-temporal disorientation. Neuroimaging showed atrophy of the left temporal lobe, ipsilateral insula, and notable involvement of the left hippocampus. Cerebrospinal fluid analysis detected anti-NMDA receptor antibodies, leading to treatment with corticosteroids and immunoglobulins. The patient was stabilized on clozapine 150 mg/day, valproate 1000 mg/day, clonazepam 1 mg/day, and monthly injectable risperidone 100 mg.

Conclusions: Discussion: HSE is a major cause of death in sporadic encephalitis cases, with a 12% relapse rate linked to viral reactivation and the development of anti-NMDA receptor encephalitis. ANMDARE, caused by anti-NMDA receptor IgG antibodies targeting the NR1 subunit, affects about 25% of HSE patients within three months. Psychiatric affective syndromes have been described both as possible initial symptoms of HSE and as long-term sequelae, but the underlying mechanisms remain not fully understood.

Disclosure of Interest: None Declared

Psychiatric comorbidity in a outpatient sample with Parkinson's disease

G. Öksüz Bildirici[1]* and E. Sönmez Güngör

Psychiatry, Erenkoy Mental Health and Neurological Diseases Training and Research Hospital, Istanbul, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.734

Introduction: Parkinson's disease (PD) is a progressive neurodegenerative disorder with a wide variety of clinical symptoms such as tremor, stiffness, and slowness. Additionally, prodromal features, psychological or cognitive problems may be observed which may complicate the treatment.
Objectives: In this study, we aimed to investigate the rate and extent psychiatric comorbidity (PC) in PD patients admitting to psychiatric outpatient clinic.
Methods: A retrospective, cross-sectional study was designed. Electronic medical records were examined for data collection of all outpatients admitting to Erenköy Mental Health and Neurological Diseases Training and Research Hospital outpatient psychiatric clinics between June 1, 2023, and June 1, 2024 who had an ICD diagnosis of G20, G21, and G22, along with their subcategories. Informed consent was obtained.The findings were grouped according to PC.
Results: Out of 37 533 outpatients, 61 outpatients (27 male, 34 female) of them were matching the inclusion criteria. Three of them had no PC and the prevalence of PC in PH was found as 95%. The patients presented with PC were chronologically categorized into 3 groups. Each of these categories was further divided into 6 subcategories based on ICD codes (F10–19, F20–29, F30–39, F40–48, G47.0–47.9, others) (See Table 1). Of note, 3 of 61 patients (4.9%) had dopamine dysregulation syndrome (DDS), characterized by addictive use of dopaminergic drugs, mood swings, compulsive and impulsive behaviors and psychosis (1).
Despite we have chronologically grouped the sample, it is not possible to determine with certainty whether the PC diagnosed before PD is a prodromal symptom or a seperate diagnosis.
Since the study was conducted at a mental health hospital, the prevalence of PC in our sample was higher than what is reported in the literature, which was expected due to sampling biases.

Image 1:

	ICD - Codes	N / %	Age (mean / median / ±SD)	Gender (F / M)
No psychiatric comorbidity		3 / 4,9 %	71,6 / 76,5 / ±11,2	1 / 2
Psychiatric comorbidity (first presentation before PD diagnosis)	F 10 - 19	1 / 1,6 %	31	0 / 1
	F 20 - 29	3 / 4,9 %	63,6 / 66 / ±4,1	1 / 2
	F 30 - 39	17 / 27,8 %	71,4 / 76 / ±8,7	13 / 4
	F 40 - 48	8 / 13,1 %	75,25 / 77 / ±7,1	5 / 3
	G 47,0 - 47,9	-	-	-
	Others	1 / 1,6 %	48	1 / 0
Psychiatric comorbidity (first presentation after PD diagnosis)	F 10 - 19	3 / 4,9 %	55 / 63,5 / ±14,9	0 / 3
	F 20 - 29	16 / 26,2 %	69,3 / 70 / ±13	6 / 10
	F 30 - 39	12 / 19,6 %	71,5 / 68 / ±10,5	6 / 6
	F 40 - 48	3 / 4,9 %	83 / 85 / ±3,6	3 / 0
	G 47,0 - 47,9	-	-	-
	Others	3 / 4,9 %	76 / 79,5 / ±7	1 / 2
Psychiatric comorbidity (Unknown time onset)	F 10 - 19	-	-	-
	F 20 - 29	-	-	-
	F 30 - 39	14 / 22,9 %	72,8 / 71,5 / ±12,1	9 / 5
	F 40 - 48	4 / 6,5 %	70 / 69 / ±5,4	1 / 3
	G 47,0 - 47,9	22 / 36 %	76,1 / 78,5 / ±8,3	14 / 8
	Others	-	-	-
Dopamine Dysregulation Syndrome	-	3 / 4,9 %	55 / 63,5 / ±14,9	0 / 3

References

Conclusions: PC is common among PD patients. It may present as prodromal symptoms of PD, may occur due to disease or medication after the onset of PD, or primary neurological and psychiatric conditions may be concomitant.
PC are often overlooked in the diagnosis and treatment and this situation complicates treatment and increases burden. Multidisciplinary approach is essential.
In our study, the highest prevalence of PC being F 30–39 is consistent with the literature. It has been determined that the most common psychiatric disorders in PD are depression (31%) (2,3).
It is noted that the most common PC before and after the diagnosis of PD were F30–39 and F20–29, respectively. It is compatible with literature. PD may present prodromal symptoms such as depression, on the contrary, it may progress with psychotic symptoms. The prevalence of psychosis in PD varies between 43-60% (4).
Special attention should be given to DDS, which is 4,9% and consistent with the literature in our sample (The estimated prevalence of 3.4–4%) (5,6). DDS is a very challenging condition to treat.

Association between the Level of Enriched Environment and serum Brain-Derived Neurotrophic Factor (BDNF) in patients with Major Depressive Disorder

A. Vega-Rosas[1]*, M. Flores-Ramos[1] and G. B. Ramírez-Rodríguez[2]

[1]Subdivisión de Investigaciones Clínicas and [2]Laboratorio de Neurogénesis, Instituto Nacional de Psiquiatría Ramón de la Fuente Muñiz, Mexico City, Mexico
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.735

Introduction: Major Depressive Disorder (MDD) is a neuropsychiatric condition whose neurobiological characteristics include alterations in brain plasticity, modulated by Brain Derived Neurotrophic Factor (BDNF). In animal models, Environmental Enrichment promotes neuroplasticity and reduces depressive-like behaviors. It has been proposed to measure the level of Enriched Environment (EE) as a protective or risk factor for the development and severity of MDD using the EE Indicator (EEI).
Objectives: Determine the relationship between the level of EE and serum levels of BDNF in participants with MDD and healthy controls.
Methods: Treatment-free MDD patients and controls were recruited, who underwent an analysis of their LES, clinical factors, and serum BDNF levels.
Results: 25 participants were recruited, of which 6 participants with MDD and the same number of controls were selected in a paired manner, who were divided into two groups:
medium and low EE. Although no differences were found between the concentration of BDNF between the groups, positive correlations were observed between social EE and BDNF, as well as negative correlations between this same domain with the Hamilton scale score for depression and the presence of this condition. No differences were found in the EE groups classified by total score between the cognitive, social and physical domains; But when breaking them down, it was observed that the sum between cognitive and social EE has a positive correlation with the serum concentration of BDNF (p=0.0451).

Image 1:

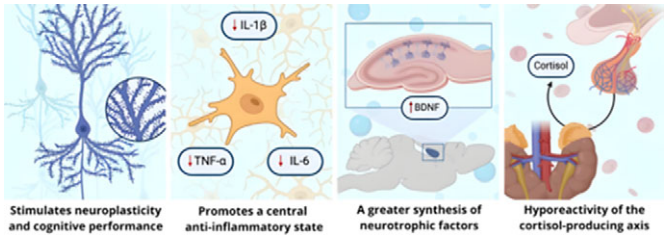

Image 2:

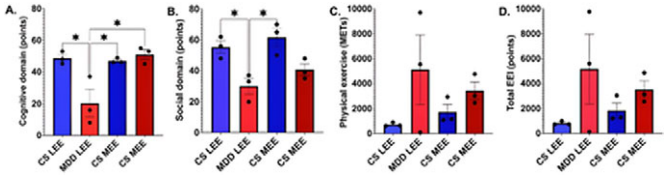

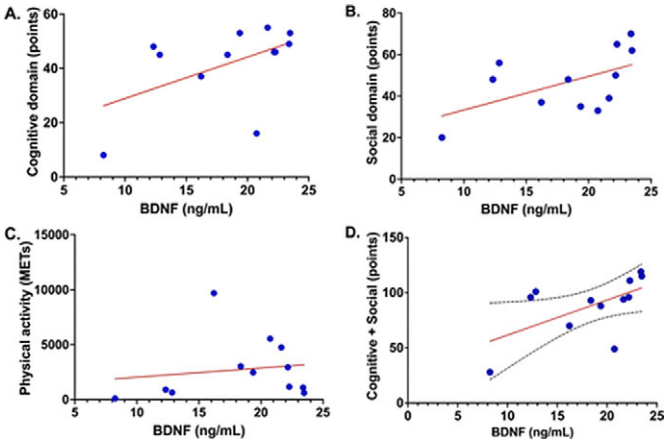

Image 3:

Conclusions: The level of EE is potentially modulating the presence and severity of MDD at a clinical level, but it can also influence at a neuroplastic level through promoting or limiting the concentration of BDNF.

Neurocognitive predictors of progression from late-life depression to all-cause dementia and Alzheimer's disease: a systematic review and meta-analysis

M. Bocharova[1]*, R. Desai[2], A. John[2], G. Charlesworth[2], J. Stott[2], A. Young[3] and D. Aarsland[1]

[1]Centre for Healthy Brain Ageing, Institute of Psychiatry, Psychology and Neuroscience; [2]ADAPT lab, Department of Clinical, Educational and Health Psychology, University College London and [3]Centre for Affective Disorders, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.736

Introduction: Late-life depression (LLD) is consistently linked with higher risk of subsequent dementia (Livingston G et al. Lancet 2024; 404: 572-628); however, predictors of progression from LLD to dementia are yet to be identified.
Objectives: In this systematic review and meta-analysis, we focus specifically on cognitive phenotypes of LLD as predictors of progression to dementia. This review aims to summarize findings from longitudinal studies exploring which cognitive domains affected by LLD are more likely to predict progression to all-cause dementia and Alzheimer's Disease.
Methods: MEDLINE, Embase and PsycINFO were searched for relevant studies published by April 18th, 2024. Study search and selection, data extraction and risk of bias assessment were performed by two reviewers separately, in accordance with the updated Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) 2020 guidelines (Page MJ et al. BMJ 2021; 372). Effect sizes for performance on neurocognitive tests were extracted and pooled separately for all-cause dementia and Alzheimer's disease (AD) outcomes.
Results: Six studies were selected for inclusion (See Fig. 1 for PRISMA flowchart). Conversion from LLD to all-cause dementia was strongly predicted by worse performance on delayed recall (SMD 0.84 [0.64 – 1.05]), immediate recall (SMD 1.02 [0.63 – 1.41]), attention/working memory (SMD 1.17[0.82 – 1.52]), processing speed (SMD 1.23 [0.37 – 2.10]), delayed recognition (SMD 1.30 [0.59 – 2.01]) and orientation (SMD 1.13 [0.90 – 1.36]); and moderately by verbal fluency (SMD 0.70 [0.50 – 0.91]), naming (SMD 0.54 [0.16 – 0.93]), and construction (SMD 0.67 [0.37 – 0.98]), but not intelligence (see Fig. 2). For AD, strong effects were observed for deficits in delayed recall (SMD 1.30 [0.59 – 2.01]), immediate recall (SMD 1.26 [0.74-1.79]), and orientation (SMD 1.64 [0.67 – 2.62]), and small to moderate for verbal fluency (SMD 0.47 [0.06 – 0.87]) and processing speed (0.66 [0.26 – 1.07]); attention or naming were not significant predictors (See Fig. 3).

Image 1:

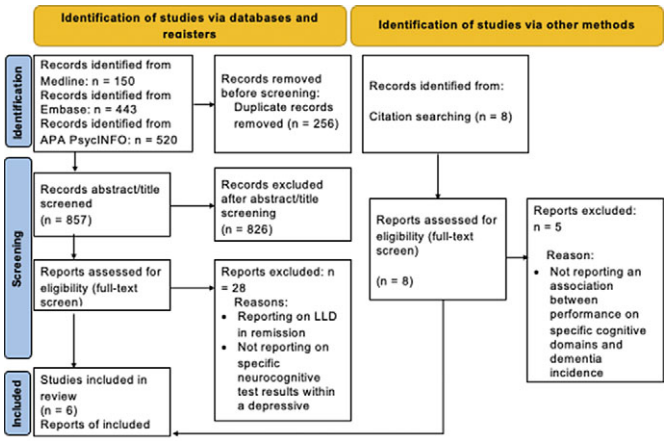

Fig. 1. PRISMA flowchart illustrating the screening and selection process for studies included in the meta-analysis

Image 2:

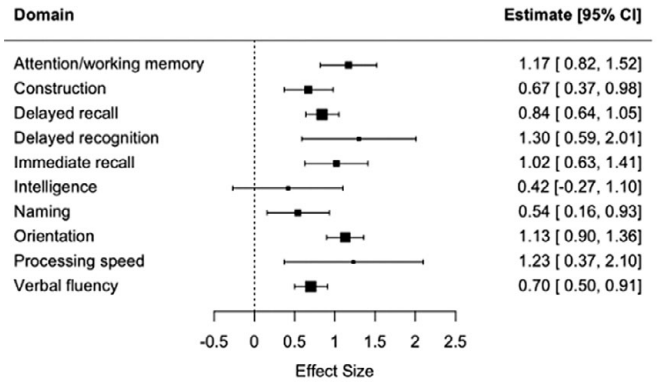

Fig 2. Forest plot showing effect sizes for mean differences in performance on neurocognitive tests at baseline between converters and non-converters to all-cause dementia

Image 3:

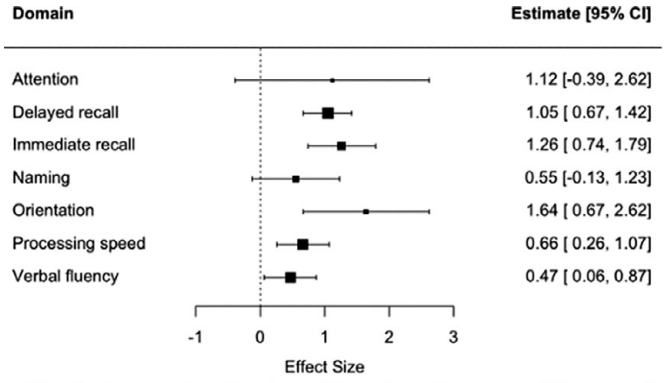

Fig 3. Forest plot showing effect sizes for mean differences in performance on neurocognitive tests at baseline between converters and non-converters to Alzheimer's disease

Conclusions: There appear to be significant neurocognitive differences across a wide range of domains within an episode of LLD between those who convert to dementia and those who do not. Future studies should aim to establish a neurocognitive profile of LLD associated with risk of conversion to specific subtypes of dementia.

Perspectives of Family Caregivers of People With Alzheimer's Disease on Caregiving Experience and Needs: A Qualitative Study

B. Şentürk Kılıç[1]*, D. Hiçdurmaz[1], Y. Ayhan[2] and E. Saka[2]

[1]Faculty of Nursing and [2]Faculty of Medicine, Hacettepe University, Ankara, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.737

Introduction: Over 55 million people currently have Alzheimer's disease (AD), with estimates predicting a rise to 78 million by 2030. The burden of AD impacts not only the affected individuals but also their families and society due to the increasing care demands. Caring for people with AD is emotionally and physically taxing. The World Health Organization emphasizes the need for caregiver support.
Objectives: This study aims to understand the caregiving experiences and needs of family caregivers for individuals with AD.
Methods: A qualitative descriptive design was used. Data were collected from 23 caregivers at a university hospital's geropsychiatric clinic. Participants were family members caring for individuals with AD for at least four hours per day. Interviews were analyzed using content analysis.
Results: Sample Characteristics: The mean age of participants was 57.82 and 57% were female. More than 85% lived with the care recipient, the average caregiving duration was 81.34 hours per week. The following themes were extracted from data collected during the interviews (Figure 1).
Themes:
Stuck in Caregiving: Participants found caring for loved ones with AD to be an unexpected challenge. Many initially missed the onset of AD due to their loved ones' previous abilities. Family conflicts over caregiving tasks, shaped by differing spiritual and cultural beliefs, were common. Caregivers faced difficulties, especially with stubborn behavior and personal care tasks.
A Life in Metamorphosis Most participants experienced profound changes in their personal lives, including social isolation and emotional turmoil. Half of the participants found meaning in caregiving, gaining new perspectives on life.
Needs: Caregivers identified specific needs, including psychosocial support, disease education, in-home care, and adult daycare services.

Image 1:

Conclusions: The gradual onset of AD delays symptom recognition, making diagnosis hard for families to accept. As caregiving demands increase, conflicts between caregiving and personal responsibilities cause stress and neglect of personal life. Despite these challenges, many caregivers find personal growth. They seek temporary care options, home assessments, and improved access to education and counseling, highlighting areas for better caregiver support.

Insights into emotional wisdom: Older adults' experiences of emotion and mental health

S. von Humboldt

William James Center for Research, ISPA – Instituto Universitário, Lisbon, Portugal
doi: 10.1192/j.eurpsy.2025.738

Introduction: Emotions wield a substantial influence on mental and physical well-being in old age, encompassing both positive and negative feelings, and effective emotional regulation is linked to aging well. Therefore, understanding the intricate connection between emotions and mental health is essential for promoting healthy aging in late adulthood.
Objectives: This study aims to explore the dimensions between emotions and mental health and the crucial role of emotional wisdom in old age, shedding light on how it influences mental health and overall well-being among older adults.
Methods: This cross-national study included 348 older adults, aged 65 and older, from Portugal and England. Participants' experiences were portrayed through semi-structured interviews, which were analyzed using content analysis.
Results: Findings revealed four themes: (1) Emotional expression (88.3%), (2) Wisdom acquisition (79.2%), (3) Emotional self-regulation (71.7%), and (4) Ability to calm oneself (68.9%).
Conclusions: Through an exploration of emotional health and wisdom across various cultural lenses, this study illuminated the complex interactions between emotions and mental well-being. It emphasizes the imperative for nuanced understanding and targeted strategies that bridge emotional aging with mental health outcomes, advocating for policies and interventions that foster holistic psychological resilience in older adults.
Keywords: Emotion; emotional regulation; emotional health; emotional wisdom; mental health; older adults.

The Impact of Childhood Maltreatment on Emotional Dysregulation in Adults with ADHD: A Comprehensive Study

G. Avci Buyukdogan[1]*, S. Sertcelik[2] and M. Nebioglu Yildiz[3]

[1]Psychiatry Clinic, Health Sciences University Istanbul Sultan Abdulhamid Han Research and Training Hospital; [2]Psychiatry Clinic, Health Sciences University Istanbul Haydarpasa Numune Research and Training Hospital, Istanbul and [3]Psychiatry Clinic, Mersin University, Mersin, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.739

Introduction: Attention Deficit/Hyperactivity Disorder (ADHD) is a neurodevelopmental disorder characterized by symptoms of inattention, hyperactivity, and impulsivity, which adversely affect an individual's functioning across various domains, including home, work, and social environments. Recent research has underscored the presence of emotional dysregulation in individuals with ADHD, contributing to significant clinical and functional impairments.
Objectives: This study aims to investigate the presence and severity of emotional dysregulation and childhood maltreatment in adults with ADHD and to explore the potential association between emotional dysregulation and childhood maltreatment within this population.
Methods: The study included 80 newly diagnosed adult patients with ADHD and 80 healthy control participants. ADHD diagnosis or exclusion was conducted using the Diagnostic Interview for ADHD in Adults (DIVA 2.0) based on DSM-5 criteria. Additionally, the ADHD group underwent screening with the DSM-IV Structured Clinical Interview (SCID-I). Participants were assessed using the Difficulties in Emotion Regulation Scale (DERS), the Childhood Trauma Questionnaire (CTQ), the Beck Depression Inventory (BDI), the Beck Anxiety Inventory (BAI), and ADHD self-report scales (WURS and ASRS).
Results: The ADHD group exhibited significantly higher total and subscale scores on the DERS compared to the healthy control group ($p<0.001$). Similarly, except for the "physical neglect" subscale, all subscale scores and the total score on the CTQ were significantly elevated in the ADHD group relative to the control group ($p<0.001$). Significant correlations were identified between the subscales and total scores of the DERS and CTQ. Depression and anxiety levels emerged as predictors of emotion regulation difficulties within the ADHD group. Across the entire sample, childhood trauma exposure (CTQ score), ADHD symptoms in adulthood (ASRS score), and levels of depression and anxiety were identified as predictors of emotion regulation difficulties.
Conclusions: The findings indicate that adults with ADHD exhibit more pronounced emotional dysregulation and higher levels of childhood maltreatment compared to healthy controls. Furthermore, childhood maltreatment appears to exacerbate emotional dysregulation in this population.

The public health and mental health implications of alcohol consumption: a focus on epidemiology and prevention strategies

M. Bivol[1]* and J. Chihai[1]

[1]Department of Mental Health, Medical Psychology and Psychotherapy, Nicolae Testemitanu State University of Medicine and Pharmacy of the Republic of Moldova, Chisinau, Moldova, Republic of
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.740

Introduction: Alcohol use remains a significant public health issue across Europe, contributing to approximately 5% of premature deaths and 25% of all fatal road accidents. The effects of excessive alcohol consumption are widespread, impacting both physical and mental health. In Moldova, as in many other regions, alcohol use is a contributing factor to a range of health issues, including alcohol dependence and alcohol-induced psychoses. This underscores the importance of comprehensive strategies to address these challenges and promote better mental health outcomes.
Objectives: This study aims to analyze the epidemiological trends of alcohol use in Europe, particularly Moldova, and its associated mental health consequences. It explores the role of alcohol in the development of psychiatric comorbidities, including depression and anxiety, and discusses strategies for prevention and treatment.
Methods: Data from WHO and local health authorities were used to assess the incidence and prevalence of alcohol dependence and alcohol-induced psychoses. The study tracked trends from 2019 to 2023 across different regions in Moldova, comparing them with European data. Furthermore, the study examined the links between alcohol use and mental health disorders like depression and bipolar disorder, highlighting the complexities of managing these co-occurring conditions.
Results: The analysis of alcohol use patterns in Moldova revealed significant regional variations in both alcohol dependence and

alcohol-induced psychoses. For instance, the Northern region experienced an increase in alcohol dependence rates from 79,2 cases per 100,000 in 2019 to 99,2 in 2023. Similarly, the prevalence of alcohol-induced psychoses in the Central region rose from 26,4 cases per 100,000 in 2019 to 35,2 in 2023. These patterns are consistent with trends observed across Europe, where alcohol consumption is frequently linked to heightened risks of developing mental health disorders, particularly depression and anxiety. Furthermore, alcohol-related psychiatric conditions pose challenges for effective treatment, often requiring integrated care that addresses both substance use and mental health.

Conclusions: The evolving patterns of alcohol use and its associated mental health consequences highlight the need for integrated, non-stigmatizing public health interventions. Prevention strategies that combine public health education, policy reform, and improved access to mental health services can help reduce the burden of alcohol use on individuals and communities. Early intervention and personalized care approaches are essential for mitigating the dual impact of alcohol and mental health issues.

Assessing Knowledge and Confidence in caring for Autistic Patients: An Observational Cross-Sectional Study of Maltese General Practitioners and Psychiatrists

N. Borg[1]*, E. Camilleri[1], L. Testa[2] and A. Grech[1]

[1]Mental Health Services, Attard and [2]University of Malta, Msida, Malta
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.741

Introduction: Autism is a neurodevelopmental condition affecting 1 in 36 people worldwide. Approximately one third of autistic individuals report a diagnosed mental health condition. Autistic people constitute 20% of referrals to outpatient psychiatry clinics. Limited knowledge and awareness of autism is the main barrier to receiving appropriate diagnostic and therapeutic support. Autistic individuals' increased mental health needs coupled with greater barriers to accessing healthcare necessitate that both primary care physicians as well as specialised services are well versed in working with these patients.

Objectives: This study aimed to evaluate knowledge of autism and self-reported confidence in caring for autistic patients amongst psychiatrists and general practitioners (GPs) in Malta. This will facilitate identification of lacunae in doctors' knowledge and advocating for greater training and awareness.

Methods: A online, anonymous questionnaire was distributed amongst psychiatrists and general practitioners in Malta as well as psychiatry and GP trainees. The questionnaire consisted of demographic questions, a 22-item modified Knowledge of Autism Scale as well as a 14-item Self-efficacy Scale targeting confidence in working with autistic patients. Data was analysed using SPSS and scores were adjusted for chance responses. Scores of the psychiatry group and the GP group were compared.

Results: The questionnaire was answered by 98 participants of which 60% (n=59) were female. The mean score on the knowledge of autism scale was 89.2% (SD=7.7) for psychiatry and 83.1% (SD=8.5) for GP. Mann Whitney U test revealed that psychiatrists fared better than GPs with an effect size of 0.35 (p=0.0003). The mean self-efficacy score was 6.7 (SD=0.4) for psychiatry and 5.7 (SD=0.8) for GP. Independent sample t-test revealed that psychiatrists scored better than GP (p=0.0003, 95% CI [0.509,1.49]). In both groups, there was no significant correlation between knowledge of autism scales and self-efficacy scales (psychiatry p = 0.26; GP p = 0.14).

Conclusions: General practitioners, psychiatrists and their trainees overall have good knowledge about autism, and feel moderately confident in working with autistic patients. As expected, psychiatrists scored better than GPs for both knowledge and self-reported efficacy. The scores obtained are comparable to studies done on a similar population in the United Kingdom. Unfortunately, Malta stilll lacks autism diagnostic services in the public sector. Nonetheless, undergraduate medical education and postgraduate training must strive to prepare doctors for working with this common cohort of patients. This will ensure a high standard of care and avoidance of adverse health outcomes or iatrogenic harm.

Happy in The Homeland? Satisfaction with Life and its Correlation with Flourishing and Affect Balance in Foreign-trained physicians who have Repatriated to Pakistan

M. Fatima[1], A. M. Hashmi[2] and M. T. Farooq[3]*

[1]Psychiatry, Dublin North Mental Health Service, Dublin, Ireland; [2]Academic Department of Psychiatry and Behavioral Sciences, King Edward Medical University, Lahore, Pakistan and [3]Psychiatry, Gartnavel Royal Hospital, Glasgow, United Kingdom
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.742

Introduction: International Medical Graduates add up to nearly one-third (23-28%) of the total physician workforce in the US, the UK, Australia, and Canada, of which around 40%-75% are from low-income countries. Pakistan is one of the three leading source countries following India and the Philippines. As per 2002 statistics by the Bureau of Emigration and Foreign Employment, only 10-15% of emigrated Pakistani physicians repatriate. No official data on the exact number of repatriated Pakistani physicians are available. This is the first original study that assessed satisfaction with life in physicians repatriating to a lower-middle-income country.

Objectives: To assess satisfaction with life (SWL) and its correlation with psychological well-being in foreign-trained, repatriated Pakistani physicians.

Methods: We conducted this cross-sectional study from April'22 to Nov'23, through purposive sampling among foreign-trained Pakistani physicians who repatriated at least three months before participating. We used the Scale of Positive and Negative Emotions (SPANE), Flourishing Scale, and Satisfaction with Life (SWL) scale. After transforming data to normality in SPSS 25 through the Distribution Fraction method, the independent sample t-test, and one-way ANOVA were applied. We assessed the correlation between affect balance, flourishing, and SWL through Pearson's correlation and ascertained the predictors of SWL through binary logistic regression (α=0.05).

Results: Of 109 respondents, the majority (70.6%) were males, from Punjab (83.5%), trained in USA/Canada (68.8%), and from the private sector (69.7%), with a Mean±SD age of 47.31±7.9. The total Mean ± SD SWL scores were 27.48± 5.03. 99 (90.8%) were satisfied with life while only 9.2% weren't. The currently married respondents (27.8±4.9 vs 24.6±5.4, p=0.04) while those from Sindh and KPK provinces had lower scores. We found a positive moderate correlation between SWL and flourishing (r=0.488), positive emotions (r=0.391), and affect balance (r=0.327) all at p=<0.001. We found good fitness of the final model with SWL as the outcome variable and Flourishing and Overall Affect Balance as predictors: Omnibus Tests of Model Coefficients (p=0.001) and Hosmer and Lemeshow tests (p=0.322). Only flourishing predicted SWL and with higher perceived flourishing, there were 1.3x higher odds of SWL.
Conclusions: This is the pioneer study to have addressed SWL and its correlation with psychological well-being in repatriated physicians, who using their skill sets and expertise, may help strengthen the healthcare system of the lower-middle income countries of origin, hence it's imperative to identify factors linked to their psychological well-being. We recommend further research on this particularly qualitative exploration.

Topiramate-Induced Phantosmia: A Case Report on Reversible Olfactory Hallucinations in Epilepsy Treatment

M. Peyioti[1]*, A. Karampas[2], V. Bountioukou[2], D. Varlamitis[2], C. Pappa[2], M. Plakoutsis[2] and P. Petrikis[2]

[1]University General Hospital of Alexandroupolis, Alexandroupolis and [2]Psychiatric Clinic, University General Hospital of Ioannina, Ioannina, Greece
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.743

Introduction: Topiramate is a widely prescribed anticonvulsant and migraine prophylactic agent, recognized for its efficacy in treating epilepsy and preventing migraines. While its use is generally well-tolerated, it is known to cause a range of side effects. However, olfactory hallucinations, also referred to as phantosmia, represent a rare and poorly documented adverse effect of Topiramate. Phantosmia involves the perception of smells in the absence of an external odor source. This case report presents the case of a woman who developed olfactory hallucinations following the re-initiation of Topiramate for epilepsy. The hallucinations resolved completely upon discontinuation of the drug. This report highlights the need for clinicians to be aware of this potential side effect.
Objectives: Topiramate is a well-established treatment for epilepsy and migraine prevention, but it can cause neurological and cognitive side effects like paresthesia, dizziness, memory issues and confusion. However, olfactory hallucinations are rare and underreported. This case report aims to contribute to the limited literature by documenting a case of reversible phantosmia related to Topiramate.
Methods: A woman presented with complaints of persistent olfactory hallucinations, perceiving unpleasant odors in the absence of any external source. Her medical history was unremarkable, apart from a diagnosis of epilepsy. After other treatments had limited success, she was started on Topiramate a couple of weeks before the manifestation of the olfactory hallucinations. Weeks after starting Topiramate, the patient began experiencing olfactory hallucinations which interfered with her daily life. The patient had no prior history of olfactory disorders, nasal pathology or psychiatric conditions and her physical examination was unremarkable. Upon investigation, no structural abnormalities were found.
Results: The patient's medication history revealed that the onset of olfactory hallucinations coincided with the initiation of Topiramate. After discussing the side effect profile of the drug, it was decided to discontinue Topiramate. Within two weeks of discontinuation, the patient reported a complete cessation of the olfactory hallucinations. A follow-up evaluation showed no recurrence of the symptoms after switching to an alternative therapy. Given the temporal relationship between the onset of olfactory hallucinations and Topiramate use, alongside the resolution of symptoms upon drug discontinuation, a diagnosis of Topiramate-induced phantosmia was made.
Conclusions: This case highlights a rare but significant adverse effect of Topiramate, olfactory hallucinations. Given the reversibility of this side effect upon discontinuation of the drug, physicians should be vigilant in monitoring for sensory disturbances in patients administered with Topiramate. Awareness of phantosmia as a potential adverse effect will allow for appropriate management, potentially preventing patient distress.

Anxiety and depression as aspects of influence on the quality of life in patients with lymphoproliferative diseases

S. V. Kuzmina

Psychiatry and medical psychology, Kazan State Medical University, Kazan, Russian Federation
doi: 10.1192/j.eurpsy.2025.744

Introduction: The high prevalence of anxiety and depression among patients with cancer has an impact on a decrease in quality of life. there are practically no studies among people with lymphoproliferative diseases, which determines the relevance of our study. Purpose: to assess the prevalence of anxiety-affective spectrum disorders and their impact on the quality of life and adaptability in patients with non-Hodgkin lymphoma (NHL), Hodgkin lymphoma (HL) and a group, including malignant neoplasm of the body of the stomach and T- and B- cellular lymphoma.
Objectives: 95 patients (women - 52, men - 44) diagnosed with NHL, HL, others were examined using a continuous sampling method.
Methods: Clinical interviews; the author's questionnaire; HADS, EQ-5D, EQ-VAS, PSM-25. STATTECH were used to process the data.
Results: The average age was 52.8±8.3 years (18 to 86). 3 groups: 1-non–Hodgkin's lymphoma, 2-Hodgkin's lymphoma, 3- malignant neoplasm of the stomach body and T- and B-cell lymphoma. In gr-s 1 and 2 (90% and 85%), no symptoms of anxiety were detected. In gr 3, clinically pronounced anxiety levels were uniformly detected in 50%. Depressive symptoms a predominantly

absence in all groups (1 - 95%; 2 - 86% and 3 - 75%) p>0.05. The assessment of quality of life: in gr 1 and 2, most of the patients noted that they experience some difficulties in the final indicator (55% and 61%), pronounced problems prevail in gr 3 (50%). The mobility of the majority in all groups does not suffer or suffers to a minor extent, 80% of all noted the absence of difficulties in self-care. "daily activity" were a statistically significant - 64% maintained it at a high level (p=0.006); Pain/discomfort is experienced by more than half of the respondents to a moderate degree 55% (p=0.003). In gr 1 and 3, the average of EQ-VAS determined at a level of more than 70 (the arithmetic mean 78 and 73), which indicates a more favorable sense of self. In gr 2 the average was determined at 68, also characterizes a high level of assessment of their general condition, in all patients with CLL, according to PSM 25, the stress level was determined to be low, indicates a state of psychological adaptation to workloads in 100%. In the gr 1, 12 people (17%) were identified with an average level of stress and reduced adaptation and need the rest for this contingent.

Conclusions: our pilot study showed that patients with lympho-proliferative diseases are characterized by a slight decrease in their quality of life, a high level of life satisfaction, good stress resistance to workloads. The main symptoms (reliably expressed in 55%), are moderate severity of pain and discomfort. The obtained data make it possible to emphasize the heterogeneity of the prevalence and severity of anxiety-affective symptoms in patients with various types of oncological diseases.

Psychological distress and unmet support needs among individuals at high hereditary cancer risk: Preliminary findings from a national needs assessment

E. Lowry[1]*, P. D'Alton[1], L. O'Driscoll[2], K. Cahill[2], D. McCartan[2] and S. Deschênes[1]

[1]University College Dublin and [2]St. Vincent's University Hospital, Dublin, Ireland

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.745

Introduction: Individuals at high familial or genetic risk of cancer face unique psychological challenges that can lead to significant distress, including worry, fear, and uncertainty about their future health and family members' risk. This study assessed mental health challenges, including anxiety and depression, in this population and explored their preferred forms of psychological support.

Objectives: To examine the prevalence of psychological distress in individuals at high hereditary cancer risk, the relationship between their current perceived support and distress, and preferred psychological support forms to inform the development of tailored mental health services.

Methods: Participants (N = 152; 95% female, 3% male, 2% non-binary; mean age = 42.6 ± 8.3) were cancer-free residents of the Republic of Ireland identified as high-risk for hereditary cancer through high-risk clinic attendance or self-reported genetic screening or family history. They completed a cross-sectional survey using standardised mental health assessments, including Generalized Anxiety Disorder-7 (GAD-7) and Patient Health Questionnaire-9 (PHQ-9), and self-reported adequacy of psychological support and preferences. Descriptive statistics and post-hoc tests were used to analyse psychological distress, support adequacy, and preferences.

Results: Moderate to severe anxiety (GAD-7 ≥10) was reported by 23%, and moderate to severe depression (PHQ-9 ≥10) by 18%. Participants reporting inadequate support had significantly higher anxiety (M = 8.1 ± 6.2) and depression (M = 6.4 ± 5.7) scores than those with adequate support (GAD-7: M = 4.2 ± 3.9; PHQ-9: M = 3.6 ± 3.9). ANOVA indicated significant differences in anxiety ($F(2,132) = 7.04$, $p = .001$) and depression ($F(2,130) = 4.68$, $p = .011$) scores across support levels. Post-hoc Tukey tests showed poorer mental health for those without support ($p < .001$ for anxiety; $p = .013$ for depression). Mental health professionals (psychologists and counsellors) were the top preferences for support, chosen by 74.8% of participants, with 47.5% selecting a psychologist and 27.3% a counsellor. An additional 12.2% preferred a healthcare professional (e.g., General Practitioner or nurse).

Conclusions: This study provides important insights into the mental health challenges faced by individuals at high hereditary cancer risk, particularly those lacking adequate psychological support. Participants reporting inadequate support experienced significantly higher levels of anxiety and depression. These findings highlight the importance of ensuring adequate psychological support services for this population and their strong preference for professional psychological care. Integrating this care into routine genetic counselling and oncology services could help to address the unmet mental health needs of this underserved population.

*Corresponding author.

doi: 10.1192/j.eurpsy.2025.746

Introduction: When an adolescent or young adult is diagnosed with cancer, they're frequently accompanied by their caregiver. Literature shows that caregivers of adolescents and young adult cancer survivors (AYACS) frequently experience high anxiety and depressive symptoms. Being these caregivers an important source of support to AYACS during this challenging journey, one question emerges: does caregivers' mental health impact AYACS' quality of life (QoL)?
Objectives: Considering this, this study examined the associations between caregivers' mental health and AYACS' QoL.
Methods: Forty-eight dyads were recruited in four hospitals and one association in Portugal. AYACS were mostly women (62.5%) and off-treatment (62.5%). They were, on average, diagnosed at 18.9 years (range: 15-25) and currently 21.98 (range: 15-38). Their caregivers were mostly women (77.1%) and, on average, 47.02 years (range: 19-76). Parent-child dyads were the most frequent. The Quality of Life Questionnaire Core-30 assessed the AYACS' QoL. Caregivers' mental health, the Hospital Anxiety and Depression Scale, and the FCR7 scale assessed caregivers' anxiety and depressive symptoms and fear of cancer recurrence, respectively.
Results: Preliminary results show that among AYACS' QoL, only low social functioning was significantly related to high anxiety and depression in caregivers. Treatment status was also significantly positively related to AYAs' social functioning and negatively to caregivers' anxiety and depression. AYAs and caregivers' ages at recruitment were also negatively correlated with caregivers' anxiety. Age of AYACS at diagnosis, living with caregiver, and type of caregiver were not related to AYACS social functioning nor caregiver anxiety and depression. A model was tested, showing that caregivers' anxiety and depression predict AYAs' social functioning, having treatment status as covariable.
Conclusions: Caregivers' mental health and treatment status were shown to be important for AYACS' QoL, especially social functioning. This supports the need to assess how caregivers are adapting to this new stage of life and provide specialized support when needed. This could indirectly have a positive impact on the QoL of AYACS. It's important that the support provided considers the diverse challenges these caregivers face, which can differ from other caregiver groups.

Effectiveness of psychosocial interventions on resilience, posttraumatic growth, and meaning in cancer survivors: a systematic review and meta-analysis of randomized controlled trials

G. Yıldız Aytaç[1]*, D. Hiçdurmaz[1] and S. Karahan[2]

[1]Psychiatric Nursing Department, Hacettepe University Faculty of Nursing and [2]Department of Biostatistics, Hacettepe University Faculty of Medicine, Ankara, Türkiye
*Corresponding author.
doi: 10.1192/j.eurpsy.2025.747

Introduction: A growing body of literature focuses on psychosocial interventions that include positive outcomes such as resilience, posttraumatic growth, and meaning in cancer survivors. A research synthesis is needed to provide a comprehensive understanding of this field.
Objectives: This systematic review and meta-analysis of randomized controlled trials (RCTs) aimed to determine the effectiveness of psychosocial interventions on resilience, posttraumatic growth, and meaning in cancer survivors.
Methods: CINAHL Plus with Full Text (EBSCOhost), CENTRAL, Pubmed, and WOS Core Collection databases were searched with no publication date or language restrictions. In addition, backward and forward citation searching was conducted in the Scopus database. The risk of bias of included studies was performed using the Revised Cochrane risk-of-bias tool for randomized trials (ROB2). The Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) approach was used for rating the certainty of evidence assessment. Analyses were carried out using IBM SPSS Statistics 28, trial version.
Results: The review included 14 RCTs with 1801 participants, published between 2005 and 2022. 10 of 14 RCTs reporting posttraumatic growth and/or meaning outcomes were involved in quantitative analysis. The overall risk of bias was judged as "some concerns" or "high" for all but one study. The pooled results suggested a small, beneficial effect in favor of psychosocial interventions on meaning "from pre-to immediately post-intervention," compared with routine care (Cohen's d = -0,298, 95% CI: -0,518 to -0,077; p = 0.008; I^2 = 0%; 319 participants; low-certainty evidence), but no sustained effects "from pre-intervention to the longest follow-up" period (Cohen's d = -0,172, 95% CI: -0,361 to 0,018; p = 0.075; I^2 = 0%; 433 participants; low-certainty evidence). No significant differences were found for posttraumatic growth between the effects of psychosocial interventions and routine care "from pre-to immediately post-intervention" (Cohen's d = -2.310, 95% CI: -5.735 to 1.115; p = 0.186; I^2 = 99.6%; 498 participants; very low-certainty evidence) and "from pre-intervention to the longest follow-up" (Cohen's d = -1.612, 95% CI: -3.847 to 0.623; p = 0.157; I^2 = 99.6%; 947 participants; very low-certainty evidence) periods. The effects of psychosocial interventions on resilience could not be pooled since only two studies existed.
Conclusions: The effectiveness of psychosocial interventions on all study outcomes is uncertain, and additional evidence are needed. Future RCTs of high methodological quality are warranted to meet the robust effects of psychosocial interventions in cancer survivors.

Reevaluating Auditory Hallucinations: Beyond the Psychotic Disorder Paradigm

V. Alves Barata[1]*, J. Bastos[1], J. Revez Lopes[2] and M. Palma[1]

[1]Hospital Prof. Doutor Fernando Fonseca and [2]Hospital de Santa Maria, Lisbon, Portugal

doi: 10.1192/j.eurpsy.2025.748

Introduction: Auditory hallucinations (AH) are frequently considered a hallmark of psychotic disorders. Even in the absence of any other features, persistent AH will fall under the DSM-5 label of Other Specified Schizophrenia Spectrum and Other Psychotic Disorder. However, AH are not exclusive to psychosis and can occur across various psychiatric and neurological conditions. Furthermore, AH have been reported in the general population, with prevalence estimates ranging from 4% to 21%. While typically transient and sporadic, a minority may experience recurrent and

persistent AH. These experiences, spanning from subclinical to pathological, have been lately understood within the framework of the "extended psychosis phenotype".
Objectives: This study aims to challenge the conventional view of AH as definitive indicators of psychotic disorders by examining their occurrence in different contexts and exploring the relevance of the "extended psychosis phenotype" in understanding these symptoms.
Methods: A literature review was conducted using the keywords "auditory hallucinations", "extended psychosis phenotype" and "phenomenology" in the PubMed and Google Scholar databases.
Results: Psychotic experiences seem to run in families, suggesting a transdiagnostic psychosis trait that may be passed down independently of emotional or thought regulation processes. As a result, psychosis - and AH in particular - can be expressed across multiple disorders, including schizophrenia, bipolar disorder, major depressive disorder, anxiety disorders, autism spectrum disorders, post-traumatic stress disorder (PTSD), and certain personality disorders, such as borderline personality disorder (BPD). Phenomenological differences of AH across these conditions remain unclear. Notably, evidence challenges the concept of 'pseudohallucinations' in BPD, showing that AH can be as severe and persistent as those in schizophrenia. Neurobiologically, AH are not always linked to abnormal dopamine activity, which calls into question the routine use of antipsychotics for all psychotic-like symptoms. Environmental and psychological factors, such as trauma, also play a role in AH, especially in BPD and PTSD. In such cases, psychosocial interventions, such as cognitive-behavioral therapy and trauma-focused therapies, are often more effective than pharmacological treatments. Finally, AH can occur in isolation, with a generally low risk of progressing into a full psychotic disorder unless accompanied by other psychotic symptoms or functional impairments.
Conclusions: The diagnostic approach to AH should be reconsidered to avoid automatic narrowing of differential diagnosis to psychotic disorders. AH can emerge from various mechanisms, including non-dopaminergic pathways. Recognizing the extended psychosis phenotype and transdiagnostic psychosis trait is crucial for understanding the continuum of psychotic experiences and improving treatment approaches.

Imagery Rescripting and Emotional Regulation: Evidence from Neuroimaging Studies

M. Ribeiro[1] and E. de Lanna[2,3]*

[1]Psychometrics, Brain Matters Research, Delray Beach, United States; [2]Psychology, Universidade Federal Fluminense, Volta Redonda and [3]Psychology, Pontifical Catholic University of Rio de Janeiro, Rio de Janeiro, Brazil

doi: 10.1192/j.eurpsy.2025.749

Introduction: Dysfunctions in mental imagery are linked to various psychopathologies, including intrusive memories from trauma, distorted perceptions of reality, and mood disorders. Therapeutic approaches, such as Imagery Rescripting (ImRs), address emotional dysfunctions by modifying mental images. ImRs is a cognitive-behavioral process requiring substantial visuospatial working memory, where distressing memories are recalled and actively altered to reduce their emotional impact. Neuroimaging studies suggest that ImRs engages mechanisms related to sensory perception and autobiographical memory recall.
Objectives: The objective of this paper is to review recent functional neuroimaging evidence on the effects of ImRs on emotional regulation. Specifically, it seeks to explore the neurological mechanisms of ImRs, focusing on its interaction with visuospatial working memory and sensory-perceptual processes to influence emotional outcomes.
Methods: An integrative review of neuroimaging studies on ImRs was conducted using databases like PubMed and Google Scholar, with keywords such as "ImRs" and "functional MRI (fMRI)." The review focused on studies from the last 10 years. Brain areas involved in emotional regulation, such as the visual cortex, amygdala, prefrontal cortex, and hippocampus, were emphasized. Both experimental and clinical studies were included to provide a comprehensive understanding of ImRs' neurobiological mechanisms.
Results: ImRs improves emotional regulation by activating brain systems involved in visuospatial working memory and emotional responses. Neuroimaging studies reveal that ImRs stimulates the visual cortex and other regions, depending on the type of mental imagery. Emotional systems responsible for primary responses like fear and reward are influenced through these sensory-perceptual processes. Since these emotional systems develop before language, ImRs effectively modifies emotional responses tied to distressing memories by altering the brain's sensory processing. The findings suggest that ImRs reshapes neural pathways related to visuospatial memory and emotional processing, with significant activation of the visual cortex, amygdala, and prefrontal cortex during rescripting. This highlights its potential as a therapeutic tool for emotional dysfunctions, such as trauma and mood disorders. However, gaps remain in fully understanding its long-term neurological effects and the complete range of brain regions affected by ImRs.
Conclusions: This review highlights the potential of ImRs in regulating emotions by influencing key brain regions. While ImRs shows promise in modifying emotional responses and neural pathways, there are still gaps in understanding its long-term effects. Future research should focus on these gaps, using advanced neuroimaging techniques and examining its effects across diverse clinical populations to fully elucidate its neurobiological mechanisms and optimize therapeutic applications.

doi: 10.1192/j.eurpsy.2025.750

Introduction: Autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) are two common neurodevelopmental conditions, whose prevalence in the general population has

significantly increased in the last decade (2.2% and 2.5%, respectively). The co-occurring prevalence of ASD and ADHD is estimated at approximately 28% (Lai et al. 2019), and the differential diagnosis between these two conditions has become increasingly challenging, especially in adulthood. For instance, both individuals diagnosed with either ASD or ADHD might present social difficulties, despite the underlying causes are notably different: individuals with ASD struggle with social approach and communication, while individuals with ADHD might show distractibility and rapid loss of interest in social activities, or even exhibit behaviors perceived as annoying or rude, such as interrupting and intruding conversations (Antshel & Russo, 2019). Most importantly, in both ASD and ADHD (and especially in women) copying strategies such as the well-known "camouflaging" were observed, to mask autistic- or ADHD-related traits, to try to fit into a society mainly structured by and for neurotypical individuals (Lai & Baron-Cohen, 2015), but ultimately affecting their physical and mental health.

Objectives: Aim of this study was to estimate the prevalence of ADHD traits and diagnosis in a sample of adult individuals with ASD without intellectual disabilities, examine sex differences in ADHD features, and explore the association between impulsivity and autistic traits.

Methods: 146 adults with ASD completed assessments for autistic-, ADHD-traits, and impulsivity. Those above the ADHD-traits cut-off underwent the Diagnostic Interview for ADHD in adults (DIVA-5).
